FiNAL 2024 Conceptual Site Model Report

Washington Works Facility
Parkersburg, West Virginia

Project Number: 60726144
Original Date: March 2024
Revised Date: December 18 2024

Table of Contents

Acronym/Abbreviation List ..... **viii**

Executive Summary ..... **x**

1.0 Introduction **1**
1.1 Purpose of the Conceptual Site Model Update 1
1.2 CSM Evaluation Approach 2
1.3 Report Organization 3

2.0 Site Environmental Setting **4**
2.1 Regional Geologic and Hydrogeologic Setting 4
2.2 Site-Specific Geologic Setting 5
2.3 Site-Specific Hydrogeology and Hydrology 6
2.3.1 Holocene Sediment Groundwater 6
2.3.2 Alluvial Aquifer 7
2.3.3 Dunkard Group Bedrock 10
2.3.4 Preliminary Water Balance Estimate 11
2.4 Updated Topography, Stormwater Basins Map and Permeable/Impermeable Surfaces Map and the Stormwater Model 12
2.5 Summary Observations on the Environmental Setting 13

3.0 Site PFAS Use and Management **14**
3.1 Overall Site Land Use and Operations History 14
3.2 PFAS Use in Site Fluoropolymer Manufacturing 15
3.3 Permitted Air Emissions and Discharges and PFAS Monitoring 15
3.4 PFAS Abatement Technologies 16
3.5 Summary Observations on the Site PFAS Use and Management 19

4.0 RCRA Corrective Action, Corrective Measures Implementation and Non-RCRA Corrective Measures **20**
4.1 RCRA Corrective Action Process History 20
4.1.1 Verification Investigation 20
4.1.2 RCRA Facility Investigation 21
4.1.3 Interim Remedial Measures 22
4.1.4 Corrective Measures Study 23
4.1.5 Statement of Basis 24
4.1.6 Final Decision and Response to Comments 26
4.2 Corrective Measures 26
4.2.1 Continued Institutional and Administrative Controls 26
4.2.2 Monitored Natural Attenuation (MNA) with Hydraulic Containment and Wastewater Treatment 27
4.2.3 Landfill Cap Operation, Maintenance and Monitoring 29
4.3 Non-RCRA Corrective Measures 30
4.3.1 Off-Site Private and Public Drinking Water Treatment 30
4.4 Summary Observations on the RCRA Corrective Action, Corrective Measures Implementation and Non-RCRA Corrective Measures 32

5.0 On-Site PFAS Conceptual Site Model....33
5.1 PFAS Sources from the Washington Works Fluoropolymer Manufacturing Processes – Figure 5-4 #1....33
5.1.1 Historical PFAS in Air Emissions (~1950s – 2013) – Figure 5-4 #2....33
5.1.2 Historical On-Site Management of PFAS-bearing Process Wastes via SWMUs and Landfills – Figure 5-4 #3....34
5.1.3 Historical NPDES Discharges to the Ohio River – Figure 5-4 #4....35
5.1.4 Process Solid Waste – Figure 5-4 #5....35
5.1.5 Process Water and Stormwater – Figure 5-4 #6 and #6A-D....36
5.1.6 PFAS in Currently Air Emissions (2013 – Present) – Figure 5-4 #7....36
5.1.7 PFAS from Leaks, Spills, Etc. – Figure 5-4 #8....36
5.1.8 PFAS in Equipment and Materials Handling – Figure 5-4 #9....37
5.2 PFAS Migration Mechanisms and Transport Pathways....37
5.2.1 Pathways to Off-Site Environmental Media – Figure 5-4 #10....37
5.2.2 Pathways to On-Site Environmental Media – Figure 5-4 #11....37
5.3 PFAS in On-Site Environmental Media....40
5.3.1 PFOA In Historical Air Emissions....40
5.3.2 PFAS in Current Air Emissions....41
5.3.3 PFOA and HFPO-DA in Soil....41
5.3.4 PFAS in Monitoring Wells....45
5.3.5 PFAS in Production Wells and the River Intake....47
5.3.6 PFAS in Outfalls....49
5.3.7 Non-Targeted Analysis PFAS Results for On-Site Environmental Media....51
5.4 On-Site PFAS Conceptual Site Model Summary and Data Gaps....52

6.0 Off-Site Conceptual Site Model....55
6.1 PFAS Sources from the Washington Works Fluoropolymer Manufacturing Processes – Figure 6-2 #1....55
6.1.1 Historical and Current Air Emissions – Figure 6-2 #2 and #4....55
6.1.2 Historical and Current NPDES Water Discharges to the Ohio River – Figure 6-2 #3A, #3B, #5A, and #5B....56
6.2 PFAS Transport Mechanisms and Migration Pathways to Off-Site Environmental Media....56
6.3 PFAS in Off-Site Environmental Media....57
6.3.1 PFAS in Off-Site Drinking Water....58
6.3.2 PFAS in Off-Site Surface Water....64
6.3.3 PFAS in Off-Site Sediment....67
6.3.4 PFOA in Off-Site Groundwater....68
6.3.5 PFOA in Off-Site Soil....69
6.3.6 PFOA in Off-Site Ambient Air....71
6.3.7 PFOA in Off-Site Rain....72
6.3.8 PFOA in Off-Site Small Mammals....72
6.3.9 PFOA in Off-Site Fish....73
6.3.10 PFOA in Off-Site Produce....74
6.3.11 PFOA in Beef and Beef Fodder....75
6.4 Off-Site PFAS Conceptual Site Model Summary and Data Gaps....75

7.0 Summary and Data Gaps of the Updated On-Site and Off-Site CSMs.....78
7.1 Summary of the Updated On-Site CSM and Data Gaps.....79
7.2 Summary of the Updated Off-Site CSM and Data Gaps.....81
7.3 Path Forward.....82

8.0 References.....83

Acronym/Abbreviation List

Acronym	Explanation
µg/kg	Micrograms per Kilogram
µg/L	Micrograms per Liter
ACO	Administrative Compliance Order on Consent
ADPs	Anerobic Digestion Ponds
AOC	Area of Concern
APFO	Ammonium Perfluorooctanoate
BG	Burning Grounds
bgs	Below Ground Surface
C-8	Historical Name for APFO
CA	Corrective Action
CEM	Conceptual Exposure Model
Chemours	Chemours Company FC, LLC
cm/sec	Centimeters per Second
CMI	Corrective Measures Implementation
CMIP	Corrective Measures Implementation Plan
CMS	Corrective Measures Study
CSM	Conceptual Site Model
DuPont	E.I. du Pont de Nemours and Company
EIM	Environmental Information Management
EPA	United Stated Environmental Protection Agency
F-143	Nomenclature for APFO
FAOC	First Amendment to Order on Consent
FDRC	Final Decision and Response to Comments
FEP	Fluoroethylene Propylene
GAC	Granular Activated Carbon
gpm	Gallons per Minute
HA	Health Advisory
HFPO-DA	Hexafluoropropylene Oxide Dimer Acid
HSWA	Hazardous and Solid Wastes Amendments
IC	Institutional Control
IRM	Interim Remedial Measures
LHWA	Little Hocking Water Association
LOD	Limit of Detection
M&M	Monitoring and Maintenance
MCL	Maximum Contamination Level
mgd	Million Gallons per Day
mg/kg	Milligrams per Kilogram
MNA	Monitored Natural Attenuation
NaOCl	Sodium Hypochlorite
ND	Not Detected
New DuPont	DuPont de Nemours, Inc.
ng/kg	Nanograms per Kilogram
ng/L	Nanograms per Liter
NH4+	Ammonium
NPDES	National Pollutant Discharge Elimination System
NQ	Non-Quantifiable
OM&M	Operation, Maintenance, and Monitoring
ORSANCO	Ohio River Valley Water Sanitation Commission

Acronym	Explanation
OSHA	Occupational Safety and Health Administration
OVS	OSHA Versatile Sampling
PCA	Principal Component Analysis
PFA	Perfluoroalkoxy
PFAS	Per- and Polyfluoroalkyl Substances
PFBS	Perfluorobutanesulfonic Acid
PFDA	Perfluorodecanoic Acid
PFDoA	Perfluorododecanoic Acid
PFHpA	Perfluoroheptanoic Acid
PFHxA	Perfluorohexanoic Acid
PFO	Perfluorooctanoate
PFOA	Perfluorooctanoic Acid
PFOS	Perfluorooctanesulfonic Acid
PFPrA	Perfluoropropionic Acid
PPA	Polymer Processing Aid
PSD	Public Service District
PT	Prior to Treatment
PTFE	Polytetrafluoroethylene
PWI	Polyacetal Waste Incinerator
PWS	Public Water System
QPR	Quarterly Progress Report
RBC	Risk-Based Concentration
RBL	Riverbank Landfill
RCRA	Resource Conservation and Recovery Act
RCRA 3013 Order	Administrative Order on Consent RCRA 3013(a) Order Requiring Monitoring, Testing, Analysis and Reporting
RFI	RCRA Facility Investigation
RL	Reporting Limit
RTC	Response to Comment
SB	Statement of Basis
SDWA	Safe Drinking Water Act
SWMU	Solid Waste Management Unit
TSCA	Toxic Substances Control Act
TWS	Transient Non-Community Water System
USACE	United States Army Corps of Engineers
UECA	Uniform Environmental Covenants Act
USDA	United States Department of Agriculture
USGS	United States Geological Survey
VI	Verification Investigation
VI WP	Verification Investigation Work Plan
VOC	Volatile Organic Compound
WVDEP	West Virginia Department of Environmental Protection
WVDHHR	West Virginia Department of Health and Human Resources
WWTP	Wastewater Treatment Plant

Executive Summary

This report documents the revisions and updates to the Conceptual Site Model (CSM) for The Chemours Company FC, LLC[1] (Chemours) Washington Works Facility (Site), located in Washington, West Virginia (Figure 1-1). An Administrative Order on Consent, the Resource Conservation and Recovery Act (RCRA) 3013(a) Order Requiring Monitoring, Testing, Analysis and Reporting (RCRA-HQ-2024-001; RCRA 3013 Order), effective December 20, 2023, requires Chemours submit to United States Environmental Protection Agency (EPA) an updated CSM, including data that have become available since the last CSM update, in accordance with EPA's systematic planning process (Environmental Cleanup Best Management Practices: Effective Use of the Project Life Cycle Conceptual Site Model, EPA 2011) within 75 calendar days of the Effective Date of the Order (Section V.48.). This report presents the updated On-Site and Off-Site CSMs for the Site completed in 2023 and includes key Site and other agencies' per- and polyfluoroalkyl substances (PFAS) results through 2023.[2]

In this report, information presented is summarized as follows:

- The geology, hydrogeology, and hydrology framework for the Site are summarized as follows. Silt, clay, and sand overlie an unconsolidated sand and gravel alluvial aquifer. Underlying this unconsolidated layer is weathered sedimentary bedrock, which is underlain by fractured bedrock.
- The pumping of high-volume, on-site production wells causes river water to recharge the alluvial aquifer.

[1] Effective February 1, 2015, the Performance Chemicals reporting segment of the E.I. du Pont de Nemours and Company completed a name and ownership change to The Chemours Company FC, LLC (Chemours). Chemours operated as a wholly owned subsidiary of DuPont until June 30, 2015. Effective July 1, 2015, The Chemours Company became a wholly independent publicly traded company; therefore, effective this date, the site is now under the operational control of Chemours. In this report, all references to work completed by DuPont refers to the E.I. du Pont de Nemours and Company that existed up until June 30, 2015.

[2] Note that in addressing EPA comments on the March 2024 submission of this report, additional relevant supporting information has been added including reports submitted to EPA between March 2024 and this submission in December 2024.

- Abatement technologies have been installed at the Site that have reduced the presence of PFAS in production well water use in the fluoropolymer manufacturing process, which has resulted in the reduction of PFAS discharge through process outfalls to the Ohio River.
- Additional abatement technologies are being installed, or are being planned for future installation, that will be designed to meet the requirements of the NPDES permit and an Administrative Compliance Order on Consent (ACO) to reduce PFAS concentrations in current air emissions and outfall discharges to the Ohio River. Ongoing PFAS sampling of the on-site sources and on-site and off-site environmental media will be used to understand the relationship between the reduction of PFAS in on-site sources and the change of PFAS concentrations in the on-site and off-site environmental media.
- RCRA CA investigations, which began in the early 1990s, and ongoing regulatory driven programs (the SDWA FAOC surveying and PFAS sampling of private and PWS drinking water program, CMI and ACO activities) have generated PFAS results over time that show that PFAS in on-site sources and in on-site environmental media have been reduced by up to several orders of magnitude. Under the SDWA FAOC, private and public drinking water sources with PFOA greater than the EPA 2016 HA of 0.070 µg/L are offered treatment by Chemours. Locations where GAC treatment systems are installed by Chemours are included in the Chemours ongoing OM&M program.

The updated On-Site CSM is summarized as follows:

- The information presented in this updated on-site CSM shows the framework for the on-site PFAS sources and the transport mechanisms and migration pathways from those sources to on-site environmental media and provides what is known regarding the presence and distribution of PFAS in on-site environmental media.
- The updated on-site CSM indicates that PFAS historically migrated and currently migrate from the Site fluoropolymer manufacturing process via air emissions and water discharges to the Ohio River, which are the primary sources of PFAS that can migrate to on-site environmental media. This does not rule out other pathways as being potential contributors. Secondary PFAS sources may be associated with equipment, material handling, leaks, and spills related to infrastructure.
- PFAS in Title V air emissions migrates to on-site surfaces via wet and dry deposition and via precipitation to stormwater then to soil and then to groundwater, or to on-site surfaces and via precipitation to stormwater and to the river water. PFAS in NPDES permitted process water and stormwater outfalls discharge to the Ohio River, and river water recharges the Site alluvial aquifer.

[3] Where used in this document, the term “air emissions” refers to Title V permitted air emissions and the term “discharges” or “water discharges” or “outfall discharges” refers to NPDES permitted discharges to the Ohio River.

Site groundwater and river water are used as process water for the fluoropolymer manufacturing processes at the Site.

- Historically the concentrations of PFAS released to on-site environmental media were higher than they are now because of several factors including the remediation of the Anerobic Digestion Ponds (ADPs) and consolidation of those materials under the Riverbank Landfill (RBL)/ADPs landfill cap, the installation of abatement technologies in the manufacturing process.
- The PFAS data presented in this report show that there are many PFAS that have been analyzed in on-site media within the past five years that are not detected above the reporting limits (RLs). PFOA and HFPO-DA are the primary PFAS detected above the RLs and are present at the highest concentration compared to other PFAS.

Data gaps that were identified while updating the On-Site CSM are as follows:

- The direction of flow between the alluvial aquifer and the underlying fractured bedrock at the Site is unproven and the presence and distribution of PFAS, other than limited results for PFOA, is unknown.
- The presence, handling, and use of common industrial articles of commerce that may contain PFAS, including sulfonate PFAS, at the Site is unknown.
- The evaluation of PFAS concentrations over time in select monitoring wells, production wells, and process and stormwater outfalls is identified here as a data gap.
- The presence and distribution of PFAS other than PFOA in Site soil are unknown.
- The presence and distribution of PFAS other than PFOA in process water from the Blennerhassett Island production wells have not been determined.
- Additional monitoring is needed to understand the presence and distribution of PFAS over time in the East Well Field header.

The updated Off-Site CSM is summarized as follows:

- The updated Off-Site CSM shows that two on-site sources of PFAS that have and continue to migrate to off-site environmental media include:
  - PFAS in air emissions, which can migrate to off-site surfaces and via precipitation to stormwater then to soil and then to groundwater, or to off-site surfaces including the Ohio River.

  - PFAS in process water and stormwater outfalls discharge to river water, and river water recharges PWS well fields adjacent to the river downstream of the Site.

The current understanding of off-site distribution of PFAS is based on the following data:

- PFOA results for environmental media sampled from within a two-mile radius of the Site in 2005 show the presence of PFOA in ambient air, rain, soil, groundwater, and drinking water is likely a result of the dry and wet deposition of Site air emissions. PFOA results for environmental media sampled from within a five-mile radius of the Site in 2011 show the presence of PFOA in soil, groundwater, drinking water, fish, and surface water used for cattle.
- PFOA concentrations in private drinking water are higher closer to the Site and to the northeast, and in general, decrease with increasing distance from the Site. However, the distribution of concentrations detected in drinking water also show that at some locations, PFAS concentrations are higher than those observed in adjacent locations.

Data gaps were identified while updating the Off-Site CSM:

- Resampling of soil and groundwater at the locations within the five-mile radius of the Site, which were sampled in 2011, for a longer list of PFAS, including PFOA, would allow for the continued evaluation of the presence of PFOA over time for some of those media and would allow for the determination of the presence and distribution of other PFAS in those environmental media.
- Sampling of surface water and associated sediment at locations within the five-mile radius is proposed to determine the presence and distribution of PFAS closer to the Site.
- Sampling of Ohio River sediments adjacent to the Site has not been performed and is proposed. If the presence of PFAS is determined to be relatively significant compared to PFAS from other transport pathways, then additional evaluation of other sediment-related media (such as suspended particles) may be proposed.
- The use, management, and disposal of PFAS-bearing articles of commerce by private drinking water well owners and evaluating this potential source is also identified as a data gap.

Activities to be conducted to fill the data gaps identified above for the On-Site and Off-Site CSMs will be proposed in the Sampling and Analysis Work Plan to be submitted within 90 calendar days of EPA's approval of these updated On-Site and Off-Site CSMs as required by Section V.48 of the RCRA 3013 Order.

It is important to note that there are several ongoing regulatory-driven PFAS monitoring programs on the Site that include sampling of monitoring wells, production wells, process water, and stormwater outfalls [i.e., CMI and the Clean Water Act Administrative Compliance Order on Consent (ACO)]. Further, the surveying and sampling of off-site private water supplies and PWSs is ongoing under the SWDA FAOC, in accordance with the terms and conditions contained in the FAOC. As new PFAS results are finalized for these programs, those data will be evaluated and used to continue to enhance and improve the On-Site and Off-Site CSMs.

1.0 Introduction

This report, the *2023 Updated Conceptual Site Model Report*, documents the revisions and updates to the Conceptual Site Model (CSM) for The Chemours Company FC, LLC[4] (Chemours) Washington Works Facility (Site), located in Washington, West Virginia (Figure 1-1). The CSM for the Site was developed in the mid-2000s based on perfluorooctanoic acid (PFOA) results for groundwater, drinking water, surface water, and cisterns at and around the Site and was first published in 2007 (Davis et al., 2007). The CSM was then updated in 2008 for the Data Assessments required by the 2005 Memorandum of Understanding between the United States Environmental Protection Agency (EPA) and the E.I. du Pont de Nemours and Company (DuPont), which owned and operated the Site at that time. The CSM was again updated by DuPont for the Correctives Measures Study in 2014 as part of the Resource Conservation and Recovery Act (RCRA) Corrective Action (CA) Program for the Site, which cumulated in the implementation of Corrective Measures as described in the Final Decision and Response to Comments (FDRC) which was signed by West Virginia Department of Environmental Protection (WVDEP) on July 9, 2015, and detailed the selected remedy for the Site. An Administrative Order on Consent [RCRA 3013(a) Order Requiring Monitoring, Testing, Analysis and Reporting (RCRA-HQ-2024-001; RCRA 3013 Order)] effective December 20, 2023, requires Chemours submit to EPA an updated CSM including data that have become available since the last CSM update, in accordance with EPA's systematic planning process (Environmental Cleanup Best Management Practices: Effective Use of the Project Life Cycle Conceptual Site Model, EPA 2011) within 75 calendar days of the Effective Date of the Order (Section V.48). This report presents the updated on-site and off-site CSMs for the Site completed in 2023, which include key Site and other agencies' per- and polyfluoroalkyl substances (PFAS) results through 2023.

1.1 Purpose of the Conceptual Site Model Update

The purpose of the CSM update is to fulfill the requirement of Section V.48 of the RCRA 3013 Order, which is to generate and submit an updated CSM addressing data that have become available since the last CSM update, in accordance with EPA's systematic planning process (EPA, 2011). Data that have become available since the last CSM update (which was in 2014 and is provided in Appendix A) include the following:

- Data for other PFAS analyzed in addition to PFOA in on-site and off-site environmental media that were generated by Chemours.
- PFAS data for off-site environmental media generated by or for other regulatory agencies, such as EPA, the United States Geological Survey (USGS), and the Ohio River Valley Water Sanitation Commission (ORSANCO).

[4] Effective February 1, 2015, the Performance Chemicals reporting segment of the E.I. du Pont de Nemours and Company completed a name and ownership change to The Chemours Company FC, LLC (Chemours). Chemours operated as a wholly owned subsidiary of DuPont until June 30, 2015. Effective July 1, 2015, The Chemours Company became a wholly independent publicly traded company; therefore, effective this date, the site is now under the operational control of Chemours. In this report, all references to work completed by DuPont refers to the company that existed up until June 30, 2015.

1.2 CSM Evaluation Approach

The approach used by Chemours to update the CSM was to choose to focus on developing two separate CSMs, one for describing on-site sources migrating to on-site environmental media, and a second that describes on-site sources migrating to off-site environmental media. For the On-Site CSM, on-site sources, on-site migration pathways, on-site environmental media, and current on-site operating conditions such as production well treatment, manufacturing operations and inline PFAS treatment, wastewater treatment operations, drinking water treatment operations were more clearly depicted such that a PFAS emissions could be more specifically traced from origin to current position in on-site environmental media. For the Off-Site CSM, PFAS in Title V permitted air emissions and National Pollutant Discharge Elimination System (NPDES) permitted outfall discharges[5] from the Site are two on-site PFAS sources that migrate to off-site environmental media.

In addition, information on the presence and concentration of PFAS in the various on-site and off-site environment media was evaluated[6]. Prior to approximately 2018, the majority of environmental media sampled both on-site and off-site by DuPont (which owned and operated the Site until July 2015), and then by Chemours (which has owned and operated the Site after July 2015) was only analyzed for the PFO anion (the entity detected by the analytical instrument) and reported as ammonium perfluorooctanoate (APFO[7]) and/or PFOA (the disassociated form of APFO in aqueous solutions)[8]. Beginning in 2018, Chemours began to analyze select samples of on-site and off-site environmental media (predominantly drinking water, groundwater, process water and stormwater) for additional PFAS analyte lists using analytical methods, such as EPA Method 537, EPA Method 537.1, EPA Method 1633 Draft[9], and non-targeted analysis using liquid chromatography coupled to high resolution quadrupole time of flight mass spectrometry. Therefore, water PFAS data evaluated for this updated CSM are primarily the results finalized by Chemours within the past five years or less depending on when analysis of longer lists of PFAS began. However, for other non-water environmental media sampled only for PFOA (for example soil, air emissions, and produce), those data are included in this evaluation regardless of the results finalization date. In addition, as

[5] Where used in this document, the term “air emissions” refers to Title V permitted air emissions and the term “discharges” or “water discharges” or “outfall discharges” refers to NPDES permitted discharges to the Ohio River.
[6] Sections IV.25 and IV.26 of the RCRA 3031 Order include lists of documents submitted to EPA that contain details of the investigations completed, which are summarized here, and references for where additional information related to those investigations can be found. Key documents are referenced as appropriate in this report and are included in the reference list in Section 8.
[7] APFO was historically known as C-8 in the 1990s and the early 2000s. Information from documents from those time periods that used the term “C-8” and are referenced in this report will used the term “C-8” in discussions presented in this report.
[8] APFO in water produces the ammonium (NH4+) and perfluorooctanoate (PFO-) ions. During Liquid Chromatography/Tandem Mass Spectrometry analysis, the PFO anion is detected at the instrument, and PFOA and APFO results are calculated based on molecular weights. Analytical laboratories initially calculated and reported APFO results, then later calculated and reported both APFO and PFOA results, and currently calculate and report only PFOA results. Early results that only reported APFO were recalculated as PFOA results in the Chemours Environmental Information Management (EIM) database. PFOA results presented in this report may have initially been reported in previous reports as APFO depending on the date of the analysis.
[9] EPA Method 1633 is still in draft form, and samples will be analyzed using the version the laboratory is certified for in West Virginia.

indicated above, PFAS results for off-site environmental media generated by or for regulatory agencies were also evaluated. PFAS abbreviations used in this document are listed in Table 1-1.

Note that in this report, where appropriate, PFOA is used instead of PFAS. Where only PFOA results exist, the term PFOA is used in discussing those results. However, it is now believed that other PFAS were likely present, even if they were not analyzed via the method used at those times. In addition, it is likely that the PFAS associated with the use of PFOA as the fluoropolymer processing aid are different than the PFAS associated with the use of hexafluoropropylene oxide dimer acid (HFPO-DA) as the fluoropolymer processing aid, although there may be overlap in the two suites of PFAS. Therefore, where appropriate, the term PFAS is used. Where PFAS, meaning other PFAS than just PFOA or PFOA and HFPO-DA, were analyzed, individual PFAS are discussed, as warranted.

1.3 Report Organization

The remainder of this report is organized as follows:

- Section 2 provides the Site environmental setting, including the regional and local geology, geohydrology, and hydrology.
- Section 3 summarizes the PFAS use history for the Site and current PFAS process discharges.
- Section 4 describes the RCRA CA, Corrective Measures Implementation, and non-RCRA Corrective Measures.
- Section 5 provides the updated On-Site CSM, including information on on-site PFAS sources, transport mechanisms, and migration pathways to on-site environmental media and data on the presence and distribution of PFAS in those media.
- Section 6 provides the updated Off-Site CSM, including information on off-site PFAS sources, transport mechanisms, and migration pathways to off-site environmental media and data on the presence and distribution of PFAS in those media.
- Section 7 summarizes the updated On-Site and Off-Site CSMs and data gaps identified.
- Section 8 lists the references cited in this report.

2.0 Site Environmental Setting

The 1,200-acre Site is located along the Ohio River in Washington, West Virginia, approximately seven miles southwest of Parkersburg, West Virginia (Figure 1-1). The Site also includes part of Blennerhassett Island, which is located upstream of the plant in the Ohio River and is where one of several Site groundwater extraction well fields is located. Immediately to the south of the Site, on the south side of State Route 892 (also referred to as DuPont Road), is the closed Chemours Local Landfill, a heavily wooded and hilly 250-acre parcel with a 20-acre, closed solid waste landfill.

The Site is located in an area of industrial, commercial and residential land use with smaller amounts of farm use and one utility property (Figure 2-1) as per the Wood County Parcel Viewer (https://data.wvgis.wvu.edu/pub/Clearinghouse/planningLanduseCadastres/Parcels/WVGISTC_2023/CountySplits/) and the West Virginia Property Assessment portal (https://www.mapwv.gov/assessment/), which includes the definitions of the land use categories.

The utility (Monongahela Power) is located between the Site and US Route 50. Immediately adjacent to the south-western boundary of the Site are two commercial warehouses and the former Sabic Plastics (formerly General Electric Plastics) facilities and Braskem properties, which are now a mix of commercial, industrial and farmland use categories. A single residential property is located adjacent to the western corner of the Local Landfill and residential properties surround the perimeter of the Local Landfill to the southwest, south and southeast. Immediately to the east is the highway interchange for State Route 892 and US Route 50 (Robert Byrd Highway), which crosses the Ohio River and Blennerhassett Island prior to entering the state of Ohio. The northern side of the Site is bounded by the Ohio River, which flows from east to west, and the state of Ohio.

2.1 Regional Geologic and Hydrogeologic Setting

The Site is adjacent to the Ohio River, which is 981 miles long, starting at the confluence of the Allegheny and the Monongahela Rivers in Pittsburgh, Pennsylvania, and ending in Cairo, Illinois, where it flows into the Mississippi River. The flow of water in the Ohio River is controlled by a series of lock and dam systems, which have greatly changed the flow of the river, making the river muddier by creating a series of very slow-moving pools rather than a free-flowing river. Flood events in the river lead to elevated river stage, but the effect of the lock and dam system is to stabilize the river stage for barge traffic. The general topography encountered in this stretch of the Ohio River Valley includes the river channel, floodplains or terraces consisting of Quaternary alluvial sediments, and the steep valley walls of the Permian-aged Dunkard Group. The Quaternary alluvial terrace sediments include primarily unconsolidated river deposits of poorly to well sorted, brown and gray sand, silts, clay and gravel. The Dunkard Series bedrock consists primarily of red and varicolored sandy shale; gray, green and brown sandstone; and minor beds of coal, claystone, black carbonaceous shale and limestone. The regional bedrock structure slopes to the east at about 25 feet per mile and is controlled by the north-south trending Parkersburg syncline (DuPont, 1992).

The facies of the Ohio River Alluvium formed in response to the glacial advances and retreats of the pre-, early-, and late-Wisconsinan and were deposited as successive phases of erosion and sedimentation of river valley alluvial materials. The coarse-grained Pleistocene alluvium was deposited as glacial outwash during the primary valley

aggradation event following the glacial scouring of the valley into the bedrock floor. During the subsequent erosion and sedimentation cycles of the Pleistocene, the glacial outwash sediments were partially removed, re-worked, and then redeposited to a lower elevation than the previous cycle, thus forming successively lower terraces. This process formed a series of Pleistocene-aged terrace surfaces within the Ohio River Valley (Figure 2-2). These surfaces were designated (youngest to oldest) as S4, S5, and S6 by Simard (1989). With each subsequent erosion and sedimentation cycle, additional fines were incorporated into the Pleistocene deposits due to continual influx of finer-grained fluvial sediments from tributaries of the Ohio River. As a result, the Pleistocene deposits become more highly re-worked and progressively finer-grained toward the center of the river valley, particularly in locations down-stream of significant tributaries (Simard, 1989). Simard (1989) also identified three minor facies of the Ohio River Alluvium including tributary deposits (silt, sand, and gravel), colluvial deposits (coarse sand, gravel, cobbles, and boulders), and eolian sand and silt deposits.

Regional groundwater supplies are obtained from the Ohio River alluvial terrace deposits and the Dunkard Group fractured bedrock. The saturated portion of the highly permeable sediments of the alluvial terraces comprise the principal regional aquifer for water supply purposes and supplies several of West Virginia's and Ohio's largest public water supply systems. Production wells completed in this aquifer have been known to yield up to 500 gallons per minute (gpm) (Schultz, 1984). Based on these high yields, numerous industrial and commercial water supply companies obtain water from the alluvial aquifer. Water from the alluvium generally is a calcium bicarbonate type with near neutral pH and high dissolved solids content, and tends to have high chloride, sulfate, hardness (as calcium carbonate), iron, and manganese concentrations (Schultz, 1984). The Dunkard Group bedrock only yields enough water for domestic and farm use. Median yields for valley, hillside and hilltop wells were 6.5, 2.0, and 3.9 gpm, respectively, and, except for a localized areas where fractures are plentiful, there is little potential for higher well yields (Schultz, 1984).

2.2 Site-Specific Geologic Setting

The Site rests on Quaternary alluvial sediments that overlie the Permian-aged Dunkard Group. The two predominant facies of the Ohio River alluvium that have been identified include coarse-grained Ohio River Alluvium (Pleistocene-aged glacial outwash deposits) and fine-grained Ohio River Alluvium [Holocene overbank deposits (Simard, 1989)].

The total thickness of Pleistocene sediments at the Site ranges from about 80 feet beneath the highest Pleistocene terrace surfaces to about 15 feet beneath the current channel of the Ohio River. Figure 2-3 provides a cross-section location map for the Site. Figures 2-4 through 2-6 show three cross sections through the Site essentially perpendicular to the Ohio River. These three cross sections were developed based on the geological units depicted in cross sections generated for the Verification Investigation (VI) and RCRA Facility Investigation (RFI), reproduced in the Data Assessments (DuPont, 2008) and provided in Appendix B. Test pit logs, soil borings, and well logs used to generate these cross sections are also provided in Appendix B[10]. Figure 2-7 shows a cross section perpendicular to the Ohio River that extends from the Site through the river to the alluvial terraces on the Ohio side of the river.

[10] Note that Appendix B includes the much of the same supporting information as was provided to EPA on September 16 and 25, 2024.

The Holocene sediments consist primarily of interbedded and laminated silt, clay, and fine-grained sand. These fine-grained Holocene sediments were deposited on the surface of the Pleistocene terraces as well as on a series of more recent floodplains, which formed in the center of the Ohio River Valley during the Holocene. The thickness of the Holocene sediments at the Site typically ranges from approximately 5 to 20 feet over the Pleistocene terrace surfaces and approximately 25 to 50 feet over the Holocene floodplains. The Ohio River deposits consist primarily of coarse-grained sand and gravel and the thickness of the alluvial sediments ranges from approximately 80 to 100 feet. The Dunkard Group (bedrock) lies at approximately 90 to 120 feet below ground surface (bgs). The Dunkard Group at the Site consists of greyish-green, fine to medium sandstone with interbedded reddish-brown clay and greyish-green siltstone, dark brown shale, and light grey medium to coarse sandstone and shale.

2.3 Site-Specific Hydrogeology and Hydrology

Three hydrologic units have been identified at the Site. Within the shallow Holocene sediments are silts and clays, which support localized zones of groundwater. Deeper down, in the older alluvial sediments, is the Ohio River alluvial aquifer, which is the primary water table aquifer. Lastly, underlying the alluvial aquifer is the Dunkard Group bedrock.

2.3.1 Holocene Sediment Groundwater

Along the southern riverbank at the Site are several monitoring wells (N04-MW02, M04-MW02, M04-MW03, P04-MW02, R04-MW02, and U04-MW01[11]) that are completed in the interbedded and laminated silt, clay, and fine-grained sand within the Holocene sediments. Groundwater elevations in monitoring wells in the Holocene sediment groundwater are frequently higher than elevations measured in monitoring wells completed in the underlying alluvial aquifer but are equal to or lower than the normal pool elevation of the Ohio River of 582 feet above North American Vertical Datum of 1988[12] (see the groundwater elevation maps in Appendix C). Note that several of these wells have been abandoned (see Section 4.1.3 for details). Seeps and springs were historically observed and noted in the Verification Investigation (1991-1992) and in the RFI (1997-1999) reports. These seeps were observed in the riverbank and were interpreted to be a result of precipitation infiltrating through the cover soil into the Riverbank Landfill materials and temporarily accumulating and flowing within the shallow overbank deposits and then discharging along the riverbank. Prior to consolidation and capping of the Riverbank Landfill, the water in these seeps and springs may accurately have been described as perched water. However, seeps are no longer observed in the riverbank subsequent to the capping of the landfill in 2012.

[11] Upon further review of the water level data reported for wells screened in Holocene sediments that were historically classified as perched water, these wells are screened in the silt, sandy silt, clay, silty clay, or clayey silt of the Holocene overbank deposits and have been reclassified as shallow Holocene wells. Note that in the tables reproduced in Appendix C, these wells are still identified as perched water.
[12] The Ohio River adjacent to the site is within the Belleville Dam project pool see page 169 of *Ohio River Navigation Charts Foster, Kentucky, to New Martinsville, West Virginia*. US Army Corps of Engineers. https://www.govinfo.gov/content/pkg/GOVPUB-D103-PURL-gpo56564/pdf/GOVPUB-D103-PURL-gpo56564.pdf.

2.3.2 Alluvial Aquifer

The alluvial aquifer near the Ohio River, which is the primary water-table aquifer in the area, occurs within unconsolidated Holocene and Pleistocene alluvium. Depth to water at the Site is approximately 60 to 70 feet bgs. The saturated zone is approximately 30 to 40 feet thick, extending to the surface of the underlying Dunkard Group bedrock. Numerous monitoring wells have been installed in the alluvial aquifer and several pumping tests have been completed as part of water supply investigations. The hydraulic conductivity of the alluvial aquifer in the area typically ranges from 100 to 300 feet/day (DuPont, 2003). Carlston and Graeff (1956) observed that in a test of 19 wells completed in the Ohio River alluvium in West Virginia, transmissivity of the aquifer ranges from 130 to 1,750 square feet per day (ft^2/day) with an average saturated thickness of 25 feet between Parkersburg and Point Pleasant, while Kozar and Mathes (2001) observed transmissivity ranging from 540 to 59,000 ft^2/day for the Ohio River alluvium and a median storage coefficient of 0.20 indicative of an unconfined aquifer. Other mean transmissivities reported include 750 ft^2/day (DuPont 2003), 4,200 (Mathes and Others, 1995) and 7,500 ft^2/day (Burgess and Nipple, 1996). The USGS (Kozar and McCoy, 2004; see Appendix D) modeled the groundwater flow in the Ohio River alluvium near the Site using porosity values ranging from 0.3 to 0.35.

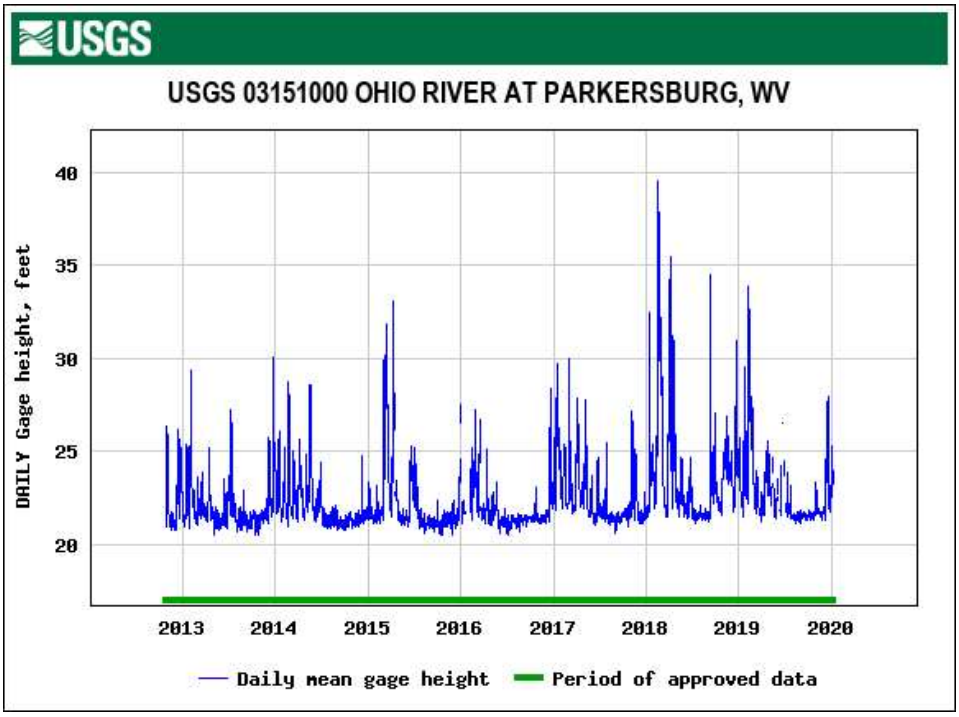
Sources of Water to the Alluvial Aquifer

Natural recharge to the alluvial aquifer comes from various sources, including the following:

- Infiltration of precipitation falling directly on the alluvium
- Lateral movement of water from the Ohio River through the alluvium
- Seepage from stream tributaries that discharge to the Ohio River
- Surface runoff from the outcrop areas of the Dunkard Group, which form steep slopes adjacent to the uppermost Pleistocene terrace.
- Permeable/impermeable surfaces

Gage elevation of the Ohio River is maintained by the lock and dam system that is intended to provide stable navigational conditions for river traffic. While there is the potential for upward variation in the river elevation (high rainfall will lead to increased river stage), the lock and dam system maintains a stable minimum river stage[13], as shown in the following graph.

[13] USGS, USGS 03151000 OHIO RIVER AT PARKERSBURG, WV. https://waterdata.usgs.gov/nwis/dv?cb_00065=on&format=gif_default&site_no=03151000&legacy=&referred_module=sw&period=&begin_date=2012-01-05&end_date=2020-12-04



As shown on the chart, the elevation of the Ohio River relative to the gage is typically about 21 feet above the gage datum of 560.60 feet NAVD88[14]. Therefore, the typical elevation of the river is approximately 581.6 feet. The elevation of the river can periodically rise during flood events, but the river has not dropped below 20 feet above gage during the period for which data are available.

Table 2-1 provides the depth to groundwater measurements and resulting elevation data for the site from the first half 2023 sampling event. These measurements are similar to others that have been collected at the facility (see the groundwater potentiometric surface maps in Appendix C). On Table 2-1, only well U04-MW01 (a shallow Holocene well) is above the elevation of the Ohio River. The other groundwater elevations are lower than the river indicating an inward hydraulic gradient.

In addition, stormwater at the Site from impermeable surfaces may migrate to permeable surfaces and recharge the alluvial aquifer. Additional information on stormwater migration at the Site is included below in Section 2.4.

Page's Run is an intermittent, ephemeral stream that originates at the Local Landfill to the south of the Site, then crosses the southwest corner of the Site and then crosses onto the adjacent former industrial property to the southwest of the Site and discharges surface water to the Ohio River. Page's Run is typically dry throughout the summer months, and the elevation of groundwater near Page's Run is below the elevation of the creek bed suggesting that it is a losing stream.

Known Uses of Groundwater in the Area

Groundwater from the alluvial aquifer is extracted for private drinking water supplies, public drinking water supplies, industrial use and agricultural use. Between Marietta (19.3 miles upstream of the Site) and Hockingport (7.7 miles downstream of the Site),

[14] Gage datum is 560.60 feet above NAVD88 per https://waterdata.usgs.gov/nwis/inventory/?site_no=03151000&agency_cd=USGS.

Chemours has identified private drinking water wells and public well fields that are located within the alluvial terraces along the Ohio River. Additional information on the private and public drinking water use is provided in Sections 4.3.1 and 6.3.1.

Withdrawals of Water from the Alluvial Aquifer

The Site has many production wells, including the following:

- Gallery Well, which draws water from below the Ohio River riverbed
- Ranney Well, which draws water from the alluvial aquifer below the riverbed
- Production wells in the west well field and the East Well field, which draw water from the alluvial aquifer
- Productions wells in the Blennerhassett Island Well Field, which draw water from the Ohio River through the saturated sediments under the island.

Water extracted from production wells on the Site and from the Blennerhassett Island well field (which are identified in Figure 2-8) is used for various purposes, including the fluoropolymer manufacturing processes at the Site:

- Water from the seven wells in the East Well Field, the four[15] wells in the West Well Field, the Gallery Well, and the 12 wells in Blennerhassett Island Well Field are untreated prior to use at the Site. Waters from these production wells are used for process water, for producing demineralized water, and for non-contact and contact cooling water for the fluoropolymer manufacturing processes.
- Well 336, also identified as AM07-PW01, is a production well in the East Well Field that is used for the Site potable water. Water from this well is the feed to the Site potable water granular activated carbon (GAC) treatment system. Treated water is then piped throughout the Site for potable water use.
- The Ranney Well is a production well for which a GAC treatment system became operational in November 2021 to reduce the concentrations of PFAS in process water for the fluoropolymer manufacturing processes. Additional details regarding this GAC treatment system are provided in Section 3.4.

The table below shows the most recently reported average daily withdrawal rate for on-site wells and well fields for each month in 2022 and the 2022 monthly average.

Month	Average Daily Withdrawal Rate (gallons per day)
January	4,531,613
February	5,168,243
March	6,479,500
April	6,832,457
May	6,681,048
June	6,274,133
July	6,188,487
August	6,338,458
September	6,283,080
October	6,170,126
November	6,005,693
December	5,487,777
2022 Monthly Average	**6,036,718**

[15] One of the five existing production wells in the West Well Field collapsed in 2003 and was abandoned.

Figure 2-9 provides the 2022 average production well or well field flows. This chart shows that in 2022 the Blennerhassett Island well field and East Well Field production wells contributed approximately 75% of the water used at the Site while approximately another 15% comes from the Gallery Well, the West Well Field and well 336. The remaining approximately 10% of the water came from the Ranney Well, which has a GAC treatment system prior to use as process water for the manufacturing plant and to support NPDES outlets permit requirements.

Groundwater Flow Direction

As part of RCRA Corrective Measures Implementation, synoptic groundwater elevation measuring events occurred quarterly in 2019 and 2020 and now occur semiannually. These quarterly and semiannual groundwater surface maps from 2019 through 2022 are provided in the annual Corrective Measures Assessment reports and are provided here in Appendix C along with historical groundwater surface maps and data tables. Table 2-1 provides the groundwater elevation measurement for the first half 2023, and the first half 2023 semiannual groundwater surface map is provided as Figure 2-10. This figure shows river recharge of the alluvial aquifer and cones of depressions around the production wells that are pumping on-site flow of off-site groundwater from the west and from the south. Groundwater elevations shown on the cross sections in Figures 2-4 through 2-6 are based on this groundwater elevation surface map and the data in Table 2-1. As shown on Figure 2-10 and figures in Appendix C, the water table in the alluvial aquifer is lower than the elevation of the Ohio River.

In 2003, DuPont revised and expanded a steady-state model developed in 1999 to evaluate groundwater flow at and near the Site, to model current Site and regional groundwater flow pathways under current (at that time) pumping conditions and to predict future groundwater migration pathways under various pumping scenarios (DuPont, 2003, included in Appendix D). To support this effort, in 2002 a synoptic groundwater elevation measuring event was completed that included both on-site and off-site production and monitoring wells in both West Virginia and Ohio (DuPont, 2003). During key stages of this model development, meetings were held with experts from EPA, USGS, and the United States Army Corps of Engineers (USACE) to review the modeling and to provide feedback. Figure 2-11 provides the modeled alluvial aquifer groundwater elevation contour map for the Site for current pumping conditions at that time. This figure shows that the water table elevations in the alluvial aquifer are lower than the Ohio River. This figure also shows that while the Site capture zone extends into the Ohio River, the current pumping conditions at the Little Hocking Water Association (LHWA) well field (located immediately in Ohio across the Ohio River from the Site (Figure 2-11) cause similar river water recharge. With few exceptions (typically U04-MW01), the groundwater elevations for Site wells shown on the figures in Appendix C are lower than the Ohio River elevation. An independent peer-reviewed and published modeling effort by the USGS (Kozar and McCoy, 2004; see Appendix D) developed in 2003 which includes the Site and adjacent areas, depicted a groundwater elevation map that is essentially the same as the one shown in Figure 2-10.

2.3.3 Dunkard Group Bedrock

and except for localized areas where fractures are plentiful,

there is little potential for higher well yields (Schultz, 1984). Note that construction details and purpose of these wells are not available.

The hydraulic conductivity of the Dunkard Group bedrock aquifer is between 0.02 and 5.6 feet/day and is strongly influenced by the presence of fractures (Table 2-2). Surficial clay and weathered shale at the adjacent Local Landfill were found to have a very low average hydraulic conductivity of 5×10^{-7} centimeters per second (cm/sec) (0.00142 feet/day) (Ellis, 1990). Competent bedrock permeability was also found to be low at about 1×10^{-5} cm/sec. These hydraulic conductivity estimates are significantly lower than those reported for the alluvial aquifer (100 to 300 feet/day - see Section 2.3.2).

Based on the limited data available, there appears to be an upward gradient from groundwater in the fractured bedrock underlying the Quaternary alluvium under the western two thirds of the Site and a downward gradient under the eastern portion of the Site. However, the groundwater model (DuPont, 2003) predicted an upward gradient from the bedrock to the overlying alluvial aquifer within most of the modeled domain, with the highest gradient predicted near pumping wells..

While Chemours believes it to be much more likely that there is an upward gradient from the underling fractured bedrock into the overlying alluvial aquifer at the Site, Chemours proposes the following to fill this data gap:

- Additional bedrock monitoring wells will be installed in well clusters with select existing alluvial aquifer monitoring wells on-site.
- Groundwater elevation measurements will be collected to evaluate the direction of groundwater flow.

2.3.4 Preliminary Water Balance Estimate

As part of an effort with the facility regarding the potential to extract additional groundwater for production purposes from the Ranney Well, a preliminary water balance calculation was performed by gathering available, measurable flows and calculating other flow estimates using simplifying assumptions. These flow volumes were estimated on an annualized basis. Appendix E provides the preliminary water balance estimate, which was submitted to EPA as an attachment in the October 17, 2024 response to comments letter. The first 16 pages of the attachment provide a review of data sources, and the last two pages are the step-by-step calculations.

- Measured parameters included the following:
  - Flows from groundwater production wells. The flow data were found in annual water use reports. Because the purpose was to support the Site with evaluating current extraction potential, flow data from the 2022 and 2023 water use reports were used.
- Estimated parameters included the following:
  - Precipitation and Evapotranspiration: The data are from United States Department of Agriculture (USDA) sources. A range of precipitation was considered and calculated. For evapotranspiration, an “actual” evapotranspiration estimate from USDA was used, but this was only applied to the vegetated acreage (this assumes all precipitation landing on impermeable areas runs off).

- Infiltration: Infiltration was estimated using input from the 2003 Model Report. Infiltration was also not applied to paved areas, which were assumed to generally run off.
- Runoff: Runoff was calculated as being the precipitation that lands on impervious surfaces and includes the excess water that did not either infiltrate or evapotranspire.

The level of certainty in the estimated values is limited because of both the variability of rainfall events and the wide range of soil conditions at the site.

Page 13 of Appendix E is the graphic flow chart of the preliminary water balance. Flows are expressed in acre-feet per year because that was the unit used for the estimated values. The two originating sources and sinks of water shown are the atmosphere and Ohio River. Based on the USDA data, the volume of precipitation to the site property was calculated to be 1,174 to 1,658 acre-feet per year (calculated as precipitation in inches per year multiplied by the acreage of the site). Evapotranspiration was calculated to remove approximately 591 acre-feet per year. The remaining precipitation is assumed to either infiltrate (194 acre-feet per year) or run off (389 to 872 acre-feet per year).

The estimate of Ohio River infiltration is an assumed calculation based on the following logic:

- Infiltration of precipitation is approximately 194 acre-feet per year. Even if all precipitation infiltrated into the aquifer that would still be less than half of the flow removed by the on-site extraction well fields (3,360 acre-feet per year).
- Because infiltration of precipitation does not account for all water being removed by the well fields, the remaining water is expected to be coming from another source, either bedrock, which has low estimated permeability, or from infiltration of water from the Ohio River into the alluvial aquifer. In the water balance, the assumption is that the shale bedrock contribution is minor relative to infiltration from the river. This contribution can be re-evaluated when the data gaps related to bedrock are filled.

Process water that is extracted from the alluvial aquifer is discharged to process outfalls (ignoring evaporative losses in the calculation), which discharge to the Ohio River. Some water from the Ohio River is directly withdrawn by surface intakes. As noted above, relative water elevations and modeling indicate that some Ohio River water is infiltrating to the aquifer to replace what is being removed by the well fields. As shown on the flow chart on page 13 of Appendix E, this forms a “continuous recirculation loop” in which water is extracted from the alluvial aquifer and discharged via outfalls, mixing with the flow of the river, and then some water from the river is concurrently being drawn back into the alluvial aquifer.

2.4 Updated Topography, Stormwater Basins Map and Permeable/Impermeable Surfaces Map and the Stormwater Model

An aerial survey of the Site was performed in April 2019, and the orthorectified imagery was used to generate topographical contours of the Site to its property boundaries. The updated topography was used in the development of the cross section provided as Figures 2-4 through 2-6.

The mapped site limits were then subdivided as preliminary maps based on the individual outfall areas, and high-resolution basin and sub-catchment maps for each Outfall were prepared as are depicted in Figure 2-12. In addition, the aerial photograph was evaluated to develop maps of permeable/impermeable surfaces. Field staff provided support to verify interpretations from the aerial photographs. Further, infrastructure drawings were evaluated to develop a map of piping and inlets. This was combined with the basin/sub-catchment maps and the permeable/impermeable surfaces map, and a stormwater model for the Site was developed that is being used to increase Site understanding of flow and volume of stormwater during precipitation events and support meeting NPDES permit PFAS limits and enhance the CSM for the Site. Model calibration is ongoing.

2.5 Summary Observations on the Environmental Setting

The observations on the environmental setting are summarized as follows:

- The geology, hydrogeology, and hydrology framework for the Site is documented here.
- Terraces of silt, clay, and sand overlie the Site alluvial aquifer, which consists of unconsolidated sand and gravel. Underlying this is weathered bedrock and bedrock consisting of shale and sandstone. Hydraulic conductivity in the alluvial aquifer is significantly higher than in the bedrock.
- USGS data show that the river elevation can increase above normal elevations but does not decrease below 582 feet (the pool elevation of the Ohio River). As shown in the water elevation maps in Appendix C, groundwater elevations in the alluvial aquifer are, with very few exceptions, consistently lower than 582 feet.
- Water elevations in the Site alluvial aquifer are lower than the river due to the pumping of high-volume on-site production wells. The amount of water being removed annually is higher than can be explained by infiltration of rainfall. Assuming that this volume of groundwater is not coming from the bedrock (shale and sandstone), then it is attributed to infiltration of river water recharging the alluvial aquifer. These production wells run continuously for Site use, supporting the assertion that there is a consistently inward hydraulic gradient preventing discharge of Site groundwater from the alluvial aquifer to the river.

One data gap was identified in this section, which is understanding the direction of flow at the Site between the alluvial aquifer and the underlying bedrock.

3.0 Site PFAS Use and Management

3.1 Overall Site Land Use and Operations History

The 1,200-acre Site is located along the Ohio River in Washington, West Virginia (see Figure 1-1), approximately seven miles southwest of Parkersburg, West Virginia. Originally, the land at the Site was used for agricultural purposes. The initial manufacturing units constructed at the Site were completed in 1948. Since the Site opened, it has expanded to include manufacturing of hundreds of products for the automotive and construction industries. The Site has produced a variety of products including the following:

- Compounded engineering plastics
- Nylon molding pellets and filaments
- Acrylic molding compounds
- Polyvinyl butyral
- Acrylic resins
- Fluoropolymers
- Polyacetal products

DuPont owned and operated the Site until July 2015 when the Site transferred to Chemours. Currently, the manufacturing operations reside on about 200 acres of the Site and span approximately a mile along the Ohio River. The Site has 13 operating and service divisions, including DuPont de Nemours, Inc. (New DuPont)[16] and Kuraray Co. Ltd. (Kuraray), which are tenant divisions with Chemours as the landlord as of 2022. Subsequently, New DuPont sold their operations to Delrin USA LLC and Celanese Corporation. Figure 3-1 shows where the Chemours, Delrin USA LLC/Celanese Corporation, and Kuraray production areas reside on the Site. The Chemours fluoropolymer and fluorotelomer manufacturing areas are located on the north-western side of the Site as shown in Figure 3-2 and produce several important commercial products including:

- TFE and HFP Monomers
- TELOMERS
- TEFLON™ perfluoroalkoxy (PFA) resin and dispersions
- TEFLON FEP resin & dispersions
- TEFLON PTFE resin & dispersions
- TEFLON PTFE granular molding resins

[16] In December 2015, Dow and E. I. du Pont de Nemours and Company announced a merger for the purpose of creating three new companies. In June 2019, the three companies completed their separation and are now known as Dow, DuPont de Nemours, Inc. (referred to in this report as New DuPont), and Corteva Agriscience LLC. In this report, E. I. du Pont de Nemours and Company (the original DuPont Company) completed all work prior to February 1, 2015. DuPont de Nemours, Inc. does not perform remediation efforts at the Site.

3.2 PFAS Use in Site Fluoropolymer Manufacturing

PFOA (CAS number 335-67-1) is a disassociated form of APFO (CAS number 3825-26-1, historically known as C-8 or FC-143) and other salts. APFO has been used in the fluoropolymer manufacturing processes as a polymer processing aid (PPA) at the Site since the early 1950s. Powdered (dry) APFO was used in the fluoropolymer manufacturing processes until the late 1980s. Liquid APFO (an aqueous solution of APFO) was used after the late 1980s. After 2000, the APFO used at the Site was produced at DuPont (now Chemours) Fayetteville Works. APFO in an aqueous solution, which forms PFOA, was used until 2012 when the Site began the transition to HFPO-DA, which was completed by 2013. HFPO-DA, known generically as GenX, used at the Site is produced at the Chemours Fayetteville Works.

3.3 Permitted Air Emissions and Discharges and PFAS Monitoring

The Site operations are subject to Clean Air Act and Clean Water Act applicability and has Title V air permits and a NPDES (permit number WV0001279) water discharge permit. The Site NPDES permit currently contains a list of requirements for the acceptance and treatment of wastewater by Chemours from Site tenants.

The NPDES permit includes discharges of industrial water (treated and untreated), stormwater, non-contact and contact cooling water, utilities (steam condensate, pump

seal water, and boiler blowdown), and groundwater infiltration to the Ohio River. There are six outfalls that discharge process water (and stormwater during storm events) which are shown in Figure 2-8. The six process water outfalls (001, 002, 003, 005, 006, and 007) include a variety of types of water discharges from Chemours and tenant operations. Table 3-1 provides a summary of the specific sources of water to each of the six outfalls. There are 13 stormwater only outfalls, which are also shown in Figure 2-8. Figure 2-12 shows the catchments and subbasins drained by each of these stormwater outfalls.

The Site's previous permit (effective September 3, 2003) included monitoring requirements for the discharge of PFOA into the Ohio River; the permit (effective September 1, 2021) included numeric limits for the discharge of PFOA and HFPO-DA and monitoring of nine other PFAS. However, Modification No. 3, effective in the second quarter of 2019, requires additional outfalls be sampled for additional PFAS as shown in Table 3-2.

3.4 PFAS Abatement Technologies

Chemours fluoropolymer manufacturing operations at the Site (Figure 3-2) currently include:

- Fine Powder Process
- Polytetrafluoroethylene (PTFE) Dispersion Process
- Fluoroethylene Propylene (FEP) Process
- FEP Dispersion Process
- Granular Process
- PFA Process K
- PFA Dispersion Process
- Telomer Area
- Monomer Area

Table 3-3 provides a summary of the product type, product applications, emission sources (air emissions or solid and or liquid wastes) and abatement technologies installed.

When DuPont transitioned to HFPO-DA in the 2012 to 2013 timeframe, additional abatement measures were installed. The key project, referred to as W-9, was a series of GAC treatment units installed in the process area. In addition, to reduce overall treatment volumes, more process wastewater was sent for recovery at the Site.

Because the Site uses HFPO-DA as a processing aid in the fluoropolymer manufacturing process, it is not intended to be present in the produced fluoropolymers. The Site is designed to remove the produced fluoropolymers from the polymerization media containing HFPO-DA and send produced wastewater containing HFPO-DA to the wastewater treatment system and then to discharge to the Ohio River via Outfall 005. Current waste streams from the manufacturing of dry products include solid wastes from the mechanical filter (which filters the wastewater to remove the solids) and filtered wastewater. In addition, miscellaneous solid wastes from the manufacturing process are also generated. The filtered solids and the miscellaneous solid wastes are incinerated at a permitted facility off-site. The filtered wastewater goes through an on-site carbon

treatment system to remove the PFOA and HFPO-DA. The treated waste streams then discharge through Outfall 002 to the Ohio River.

Well water prior to its use in the fluoropolymer manufacturing processes. Water extracted from production wells on the Site and from the Blennerhassett Island well field (which are identified in Figure 2-8) is used for various purposes including the fluoropolymer manufacturing processes at the Site. Site groundwater contains PFAS; therefore, process water obtained from on-site production wells also contains PFAS prior to its use in fluoropolymer manufacturing. Construction of a 1,750 gpm treatment system for the Ranney well was completed by November 2021. The purpose of the treatment system was to remove PFAS prior to use as process water for the manufacturing process and to support NPDES outlets permit requirements. The objective was to remove PFOA and HFPO-DA with GAC and have pretreatment to greatly reduce concentrations of manganese, iron, and suspended solids. The project installed pretreatment process equipment for chlorination and sand filtration, and GAC filtration for PFOA and HFPO-DA removal. The project scope included the following:

- Replacing the existing Ranney Well pumps and routing new piping to and from the new treatment facility.
- Installing sodium hypochlorite (NaOCl) solution tanks and an injection system for oxidizing iron and manganese, and for disinfection prior to distribution.
- Installing Greensand+ filters to remove manganese, iron, and suspended solids.
- Installing two sets of Calgon model 12-40 GAC filters in parallel to remove PFAS and other organics.
- Installing a filter backwash system including a new holding tank.
- Installing sand drying beds to filter and capture the suspended solids from the backwash water.
- Erecting a new structure to house the Greensand+ and GAC filters.

The project was successfully completed in time for the regulatory compliance schedule in November 2021. The Site now conducts routine monitoring and GAC change-outs as part of normal site operations. Table 3.4 provides the results from the GAC treatment of the Ranney well that goes into the process water header to the plant. Table 3.4 also provides results for the polish GAC filters, which are additional carbon filters installed after the treated Ranney water in September 2024 on piping specifically for use in the PFA Line 2 manufacturing process. Table 3.4 shows that the GAC treatment system and the polish GAC treatment filters effectively removes PFOA and HFPO by four orders of magnitude from the process water prior to use (generally to less than 20 or 50 parts per trillion or 20 or 50 nanograms per liter [ng/L]) compared to the raw water PFOA and HFPO-DA concentrations. For the Ranney Well GAC treatment system, carbon in the lead bed is replaced when the discharge reaches 50% of the raw water concentration.

The lead bed with the new carbon then becomes the lag bed, and the lag bed is then moved into the lead bed position. Reductions in PFOA resulting from the GAC treatment installation have resulted in reductions of PFOA concentrations discharging via outfalls to the Ohio River. Figure 3-3 provides graphs of PFOA and HFPO-DA concentrations over time in Outfalls 002 and 005. Outfall 002 discharges process water from the fluoropolymer manufacturing area, while Outfall 005 discharges water from the wastewater treatment plant, which includes process water from the fluoropolymer manufacturing area, and discharges the largest volume of water of the six Outfalls. In Figure 3-3, PFOA over time are shown on the left side of the figure and HFPO-DA over time are shown on the right side of the figure. Where two graphs are shown, the second graphs are expanded views of the first graphs. Note that the date range and concentration scale are unique to each chart. In these charts, the transition from PFOA to HFPO-DA is indicated, as well as the Ranney Well GAC system installation.

Chemours also began a program of installing tertiary abatement systems to reduce HFPO-DA in air emissions at the Site. Examples include adding GAC treatment to the Fine Powder and PFA Process K in the past three years.

EPA issued an Administrative Compliance Order on Consent (ACO) under Section 309(a) of the Clean Water Act, 33 U.S.C. § 1319(a) to Chemours on April 5, 2023. Section III.44. requires Chemours to implement the Sampling Plan (Exhibit 3 of the Order) to characterize the nature of the stormwater runoff and effluent wastewater leaving the Site by conducting specified PFAS sampling to identify and quantify PFAS discharges at each permitted Outlet[17] using draft EPA Methods 1621 (for absorbable organic fluorine) and 1633, total oxidizable precursor assay and non-targeted analysis. In August 2024, Chemours submitted the report that contained the results for the stormwater runoff and effluent wastewater sampling event (see Appendix G). In summary, the new results show similar trends in the presence and distribution of PFAS in those samples compared to other process water and stormwater data presented in this report in Section 5.3.6. For the NTA results, only one of the 20 samples, a stormwater sample collected at Outlet 016, showed the presence of suspect analytes, and only one suspect analyte was identified. Nineteen of the 20 process water effluent and stormwater outlet samples were shown to have no non-targeted compounds identified, which indicated that there are no unknown PFAS or precursors present in these samples at the level of detection for the method. The results for those stormwater and process water samples are discussed in more detail in Section 5.3.7 along with the results of an earlier NTA data set.

Further, Section III.46 of the ACO requires Chemours to submit an Alternatives Analysis and Implementation Plan for the treatment of HFPO-DA and PFOA to ensure such discharges meet numeric effluent limits at each of outlets 001, 002, 005 and 006. Specifically, the alternatives to be considered include use of additional technologies capable of meeting existing effluent limits (which include, but are not limited to, ion exchange, granular activated carbon, reverse osmosis, and any additional current

[17] The ACO uses the term “Outlet” instead of “Outfall.” The numbering convention of “Outlets” matches that of the “Outfalls”.

technologies capable of treating PFAS) and may also include use of enhanced facility management practices that would prevent or minimize the amount of PFOA or HFPO-DA that can reach and be discharged from the Outlet. The Alternatives Analysis and Implementation Plan was submitted in August 2023. To date, the agencies have not completed their review.

3.5 Summary Observations on the Site PFAS Use and Management

Summary Observations on the Site PFAS Use and Management include the following:

- Additional abatement technologies are being installed, or are being planned for future installation, that will be designed to meet the requirements of the NPDES permit and the ACO and to reduce PFAS concentrations in current air emissions and outfall discharges to the Ohio River. Ongoing PFAS sampling of the on-site sources and on-site and off-site environmental media will be used to understand the relationship between the reduction of PFAS in on-site sources and change of PFAS in the on-site and off-site environmental media.

One data gap identified in this section is that the presence, handling, and use of these common industrial articles of commerce which may contain PFAS, including sulfonate PFAS, at the Site are unknown and are identified here as a data gap.

4.0 RCRA Corrective Action, Corrective Measures Implementation and Non-RCRA Corrective Measures

This section describes the RCRA CA, Corrective Measures Implementation, and non-RCRA Corrective Measures.

4.1 RCRA Corrective Action Process History

4.1.1 Verification Investigation

In March 1985, EPA requested that DuPont provide information on the Site's solid waste management units (SWMUs). On June 5, 1985, DuPont submitted information on 14 SWMUs. Subsequently, EPA under the RCRA Hazardous and Solid Wastes Amendments (HSWA) issued a permit (RCRA Permit WVD 045 875 291) requiring that a VI be completed on six of the 14 SWMUs. In accordance with the requirements of the permit, DuPont submitted the Verification Investigation Work Plan (VI WP) on December 14, 1990 (DuPont, 1990). After addressing EPA comments on the VI WP, in the winter of 1991, DuPont conducted the VI for five of the six SWMUs:

- SWMU A-1, the Local Landfill: This landfill is located adjacent to the southern edge of the Site (Figure 2-1). Wastes disposed of at the landfill include inert acrylic polymer sludge, inert mixed plastics, calcium chloride sludge, small quantities of RCRA hazardous ash, and ash from power generation and burning plant trash. Wastes from the fluoropolymer manufacturing processes were not disposed of at this landfill. The landfill operated from 1964 until 1996.
- SWMU A-3, Riverbank Landfill (RBL): This on-site landfill that received powerhouse ash, incineration ash, plastics, rubble, plant trash and approximately 200 drums of solid material between 1948 and the late 1960s.
- SWMU B-4, Anerobic Digestion Ponds (ADPs): This SWMU consisted of three ponds (one dating from the 1950s and two dating from the 1970s) where waste from the fluoropolymer manufacturing process were managed until 1988. The footprint of the ADPs overlapped the footprint of the RBL (Figure 2-8).
- SWMU C-6, Polyacetal Waste Incinerator (PWI): The PWI was an incinerator that operated between 1959 and 1990. Materials incinerated included off-specification polyacetal polymer and other non-hazardous solid waste packaging materials. Some finishing area wastes and non-hazardous chemical area wastes were also burned in the incinerator. Wastes from the fluoropolymer manufacturing processes were not managed at the PWI.
- SWMU H-14, Burning Grounds (BG): The BG operated between 1948 and 1965 and was an area used for open burning of plant trash and organic liquids including acrylic monomer slurries, polyvinyl butyral ink slurries, high boiling point fluorocarbon compounds, and solvents. Solid wastes included paper, trash, and plastic.

Detailed information regarding the sixth SWMU, SWMU F-11 (two deep injection wells), was included in the VI WP and in a September 1991 letter, WVDEP approved the closure plan; therefore, no investigation was ultimately required as part of the VI.

The ADPs consisted of three digestion ponds co-located within the western portion of the RBL. One of the ponds dated from the 1950s, and the two other ponds dated from

the 1970s. The ponds were used for the containment and treatment of aqueous waste from the fluoropolymer manufacturing process and were used through 1988. The ponds were of earthen construction, were approximately 6 feet deep, and had a combined estimated volume of 3 million gallons. There were no outfalls from the ponds. Consequently, the ponds were operated to not overflow. The aqueous waste was periodically removed and shipped to another DuPont location for final treatment. In 1988, the ponds' contents, the upper few feet of clay liner, and pond-berm material were removed and disposed of at the DuPont Dry Run Landfill. Post excavation soil analytical results (Appendix C of the VI) from soils below the three pond bottoms showed between 66 and 110 parts per million of C-8. The ponds area was then backfilled and capped with topsoil and vegetated with grass.

During the VI, DuPont determined that C-8 had been released from the ADPs to underlying soils and groundwater and recommended additional investigation. Although no fluoropolymer wastes were managed at the RBL due to the overlapping footprints of these two SWMUs and the presence of C-8 in soils and groundwater near the RBL, DuPont also recommended additional investigation of the RBL for C-8, as well as select volatile organic compounds (VOCs) associated with landfilled materials. The BG was also recommended for additional investigation due to the presence of select VOCs in soil and groundwater near the SWMU. No further investigation was recommended for the PWI. However, DuPont recommended closure of the PWI in accordance with an approved closure plan.

The findings of the VI also recommended that no further investigation was needed at the Local Landfill as it was operated and permitted in accordance with WVDEP Permit #34394, had a combined WV Solid Waste/NPDES permit application pending and would eventually be closed under WV Solid Waste Management Regulation.

4.1.2 RCRA Facility Investigation

In accordance with the RCRA Permit and a letter from EPA dated May 1997, DuPont conducted a RFI for the RBL, ADPs, BG and PWI SWMUs during 1998 and 1999. The PWI was further investigated in the RFI based on comments from the EPA in the VI and the presence of chromium was evaluated in soil.

Based on the findings of the RFI (DuPont, 1999), the RBL and ADPs SWMUs (commonly referred to as the RBL/ADPs SWMUs because of the overlapping footprints of these two units) were carried forward into a Corrective Measures Study (CMS) because select VOCs and PFOA released from these SWMUs exceeded appropriate groundwater and soil screening level criteria[18]. Although neither PWI nor BG was specifically identified in the RFI as "no further action," these two SWMUs were not carried forward in the CMS (URS, 2014) because the RFI risk evaluation identified no complete exposure pathways for potential human or ecological receptors at these units.

The RFI was approved by EPA in 2006 (see Appendix H). Subsequently, an Interim Remedial Measures (IRM) study was completed in 2007, followed by the CMS completed in 2014. WVDEP issued the Statement of Basis (SB) and the FDRC in 2015. Chemours submitted the Corrective Measures Implementation (CMI) Plan (CMIP) in

[18] The risk-based human health protective soil screening level applied at that time was 240 parts per billion (ppb). This screening level was established by the West Virginia Department of Environment Ammonium Perfluorooctanoate (C8) Assessment of Toxicity Team (CATT) in August 2002.

2017, which was approved by WVDEP in 2018 and was implemented in 2019. Sections 4.1.3 through 4.2 provide additional detail for these programs.

4.1.3 Interim Remedial Measures

An IRM study was completed in 2007 to evaluate the possible remedial options for the select VOCs and PFOA related to the RBL/ADPs SWMUs, including the methylene chloride seep at the RBL. The IRM study evaluated various potentially applicable IRM alternatives to mitigate potential risks posed by the RBL/ADPs SWMUs. An engineered cap system on the RBL slopes and over the ADPs with supplemental tie-ins to existing cover in the production area was ultimately recommended in the *Interim Measures Selection Report* (DuPont, 2008) as the preferred IRM for the RBL/ADPs SWMUs. In addition to the engineered cap system, institutional and administrative controls were proposed to minimize the impact to human health and the environment from the PFOA and select VOCs present in the RBL/ADPs SWMU materials or in the underlying soils and groundwater.

The IRM was approved by EPA on February 22, 2011. Construction activities were implemented from September 2011 to December 2012, and the *Riverbank Landfill IRM Completion Report* was submitted in December 2013. The engineered cap system was designed and constructed to meet the intent of the performance requirements detailed in the WVDEP Title 33, Series 1, Solid Waste Management Rule (W. Va. Code §22-15-1) regulations for a Type F Industrial Landfill (WVDEP, 1996). Consolidation of fill materials located on the Ohio River terrace to the existing landfill slopes reduced the footprints of the RBL and ADPs SWMUs and minimized the potential of erosion and for human or ecological contact with PFOA- and VOC-bearing SWMU materials. Note that when the ADPs were closed in 1988, an engineered cap system was installed on the landfill slopes to supplement the existing cover in the adjacent manufacturing areas which eliminated the potential for human or ecological contact with the SWMU materials and impacted subsurface soils. This system also minimized infiltration of surface water through the landfill material, resulting in a reduction in the potential migration of constituents from the RBL/ADPs SWMUs. Several monitoring wells in this area were abandoned as part of the capping activities.

In addition to the engineered cap system, institutional and administrative controls were implemented to ensure protection of human health and the environment from the PFOA and select VOCs present in the RBL/ADPs SWMUs and in the underlying soils and groundwater. An excavation permit process was established to ensure the safety of site workers. As part of this process, excavation permits are required prior to conducting any intrusive activities, including excavation at the SWMUs. This excavation permit process also ensures that no future intrusive activities occur within the engineered cap area without prior consultation with site personnel responsible for the engineered cap.

During cap construction, the existing facility security fence, which limited access to the Site, was removed. After completion of the engineered cap system, a new security fence was constructed at the top of slope along the existing manufacturing area. The new fence was a 7-foot-high chain link fence with three strands of barbed wire. Security lighting was also installed. Following the security fence construction, a fiber optic intrusion detection system was also installed on the fence to limit access to the Site. These activities were completed by January of 2013. There are security patrols, security cameras and security lighting along the toe of the landfill that monitor the area and reduce the likelihood of trespassers.

The engineered cap system requires maintenance and monitoring to maintain its effectiveness. Additional details describing the ongoing RBL/ADPs engineered cap inspection and maintenance required by the Corrective Measures Implementation Plan is provided in Section 4.2.3.

4.1.4 Corrective Measures Study

URS Corporation (URS, now AECOM[19]), on behalf of DuPont, prepared the CMS report for the Site. The CMS focused on two SWMUs, the RBL and the ADP.

A CMS, as defined by EPA, is a study that identifies and evaluates potential remedial alternatives to address releases from SWMUs at a facility. Remedial decisions are made by comparing possible remedies against threshold criteria and balancing factors. However, the CMS, with approval from EPA, took a more focused, streamlined approach. It presented the remedy already implemented at the Site and described the remedy and monitoring proposed to manage SWMU-related releases to groundwater to ensure the ongoing protection of human health and the environment. The specific objectives of this streamlined CMS were as follows:

- Summarize the IRM and its implementation.
- Present the current conditions at the Site following the implementation of the IRM.
- Present the updated CSM and Conceptual Exposure Model (CEM) for the Site based on the current (post-IRM) conditions.
- Describe the remedy and monitoring proposed to meet the corrective action objectives for the Site.

The specific remedy and monitoring proposed for this Site were as follows:

- Propose the IRM implemented at the RBL and the ADPs as the final remedy.
- Continue the various water treatments and institutional and administrative controls currently in place to ensure the protection of human health and the environment at the Site.
- Maintain hydraulic control of groundwater by way of pumping production wells as a means to manage SWMU-related releases to groundwater and to ensure protectiveness of human health and environment until such time as an alternative means of control is proposed by DuPont and approved by EPA or contaminants in groundwater are reduced to below Federal Maximum Contaminant Levels (MCLs).
- Develop and implement a groundwater monitoring plan as part of the final remedial measure (after the CMS is approved) to ensure the ongoing protectiveness of the elements of the remedy.

The CMS detailing the proposed remedy for the facility was submitted in August 2014, was revised to address EPA comments and was resubmitted in October 2014. The CMS was approved by EPA on February 12, 2015 via email communication from Bill Wentworth of EPA to Andrew Hartten of DuPont (now Chemours).

[19] AECOM Technical Services, Inc. (AECOM) completed acquisition of URS Corporation on October 16, 2014.

4.1.5 Statement of Basis

WVDEP issued the SB in April 2015. WVDEP's proposed remedy was comprised of a program of monitored natural attenuation[20] in conjunction with the continued control, capture, and treatment of contaminated groundwater and the implementation of institutional controls (ICs). Specifically, WVDEP's proposed remedy included the following:

- *"Proposed Continued Institutional and/or Administrative Controls: ICs are administrative and legal controls that minimize the potential for human exposure to contamination and/or protect the integrity of the proposed remedy by limiting land or resource use. Because concentrations of some contaminants remain in site soil and groundwater above residential use, the proposed remedy required compliance with land and groundwater use restrictions. Specifically, the proposed remedy included the following:*
  - *Except for the production water that is already approved for treatment and use as potable water at the site, groundwater at the site shall not be used for any purpose other than 1) industrial use[21] and non-contact cooling water; and 2) the operation, maintenance, and monitoring activities required by WVDEP and/or EPA unless it is demonstrated to WVDEP, in consultation with EPA, that such use will not pose a threat to human health or the environment or adversely affect or interfere with the selected remedy and WVDEP, in consultation with EPA, provides prior written approval for such use.*
  - *The property shall not be used for residential purposes unless it is demonstrated to WVDEP, in consultation with EPA, that such use will not pose a threat to human health or the environment or adversely affect or interfere with the selected remedy, and WVDEP, in consultation with EPA, provides prior written approval for such use.*
  - *All earth moving activities, including excavation, drilling, and construction activities in the areas at the plant where any contaminants remain in soils above EPA's Screening Levels for non-residential use or groundwater above Federal Maximum Contamination Levels (MCLs)/Tap Water risk-based concentrations (RBCs) shall be prohibited unless it is demonstrated to WVDEP, in consultation with EPA, that such activity will not pose a threat to human health or the environment or adversely affect or interfere with the selected remedy, and WVDEP, in consultation with EPA, provides prior written approval for such use.*
  - *The property will not be used in a way that will adversely affect or interfere with the integrity and protectiveness of the selected remedy.*
  - *No new monitoring wells will be installed on the property unless it is demonstrated to WVDEP and EPA, that such wells are necessary to implement the selected remedy and WVDEP provides prior written approval to install such wells.*

[20] Note that in the CSM, DuPont proposed a monitoring program coupled with a plan for continued hydraulic controls of constituents in groundwater. Monitored natural attenuation was not proposed.
[21] In this context, industrial use includes existing and potential future safety showers and eyewash stations. Process water may be used for these purposes as per the Chemours Washington Works Environmental Health and Safety Procedure 537 (Revised January 15, 2020).

  - *No new production or drinking-water wells will be installed on the property without prior approval by the West Virginia Department of Health and Human Resources local Health Department. WVDEP and EPA will be notified of any new production or drinking-water well installation.*
  - *The Owner agrees to provide WVDEP and EPA with a "Certified, True and Correct Copy" of any instrument that conveys any interest in the property or any portion thereof.*
  - *The Owner agrees to allow the WVDEP, EPA, and/or their authorized agents and representatives access to the property to inspect and evaluate the continued effectiveness of the final remedy and, if necessary, to conduct additional remediation to ensure the protection of the public health and safety and the environment based upon the selected remedy as detailed in the FDRC.*

- *Related to the proposed continued institutional and/or administrative controls listed above, WVDEP proposed in the remedy that the Site file an environmental covenant pursuant to the West Virginia Uniform Environmental Covenants Act to implement the land and groundwater restrictions necessary to prevent human exposure to Site contaminants. However, WVDEP also stated that if WVDEP determined that additional IC/GACs were necessary to protect human health or the environment, WVDEP had the authority to require and enforce that corrective action.*
- *Proposed Monitored Natural Attenuation with Continued Production Plant Well Pumping and Hydraulic Containment: This component of the proposed remedy required that the Site continue production well pumping a 4 million of gallons per day to provide hydraulic containment of groundwater on-site and allowed for the Site to request to WVDEP a change in production well pumping provided the Site demonstrated to WVDEP that hydraulic control of on-site groundwater was maintained. Further, it required the Site maintain a groundwater monitoring program to demonstrate that an inward gradient is maintained and that the contaminant mass is being reduced through natural attenuation. The facility was also required to continue the groundwater capture and treatment program and identify sources area of contamination when possible and apply a remediation technique to reduce impacts from the source areas where possible.*
- *Ex-situ Treatment of Waste Process Water at the Wastewater Treatment: This part of the proposed remedy required continued ex-situ treatment of process wastewater at the site wastewater treatment plant was required until the concentrations in groundwater were reduced to their MCLs.*
- *Treatment of Potable Water: As part of the proposed remedy, the Site was also required to continue to treat groundwater used for potable water at the Site for PFOA and VOCs removal until groundwater PFOA and VOCs concentrations were reduced to their MCLs.*
- *RBL/ADPs Monitoring and Maintenance (M&M): The Site was also required to perform monitoring and maintenance of the RBL/ADPs engineered cap system through the life of the Site to maintain its effectiveness and protectiveness, and to ensure the health and safety of site workers and to reduce the potential for trespasser exposure to SWMU materials."*

The Statement of Basis also included a section that provided a description of the criteria used by WVDEP to evaluate their proposed remedy. That description included the WVDEP evaluation of three decisions criteria as general goals and an evaluation of seven balancing criteria.

The Statement of Basis also notified interested parties of the 30-day comment period from the date the notice was published in a local newspaper and the process for submitting comments.

4.1.6 Final Decision and Response to Comments

Subsequently, WVDEP received no comments during the 30-day public comments period, which ran from May 11 through June 10, 2015. The FDRC was signed by WVDEP on July 9, 2015, and detailed the selected remedy for the Site, which was unchanged from the proposed remedy in the SB.

4.2 Corrective Measures

Chemours submitted the CMIP (AECOM, 2018) to WVDEP in November 2017. On October 3, 2018, Chemours submitted the Response to Comments (RTCs) and Revised CMIP to WVDEP, and WVDEP approved the CMIP on October 29, 2018.

The selected remedial measures for the Site identified in the FDRC and in the approved CMIP are as follows:

- Continued ICs.
- Monitored Natural Attenuation (MNA) with continued production well pumping and hydraulic containment and with continued treatment of captured groundwater via the on-site wastewater treatment plant (WWTP).
- Ex-situ treatment of waste process water at the WWTP.
- Treatment of potable water from drinking water wells.
- RBL/ADPs engineered cap inspection and maintenance.

CMI began in January of 2019. Annual Corrective Measures Assessment (CMA) reports were submitted in 2019 through 2022 (AECOM, 2019, 2020, 2021, and 2022) and the 2023 CMA report is anticipated to be submitted in May of 2024. The sections that follow provide a summary of recommendations identified in the annual reports and approved by WVDEP, and an assessment of the remedy effectiveness to date.

4.2.1 Continued Institutional and Administrative Controls

According to the FDRC, the purpose of the ICs required for the Site is to "…maintain protection of human health and the environment over time by controlling exposure to the subsurface and groundwater to ensure long-term effectiveness." ICs required for the Site are listed above in Section 4.1.5., as established in the SB and FDRC (WVDEP, 2015a and 2015b).

The ICs also include a mechanism to guarantee that the controls are transferred as part of any property transaction involving affected areas of the facility. This guarantee would be implemented via an environmental covenant that complies with the West Virginia Uniform Environmental Covenants Act (UECA) [West Virginia Code Chapter 22 (Environmental Resources) Article 22B]. Due to the COVID outbreak in 2020 and 2021,

progress on the development of the draft UECA stalled. Development of the draft UECA began in 2022 and continued in 2023.

ICs required for the Site, as established in the SB and FDRC (WVDEP, 2015a and 2015b), are in place and the Site is in compliance. This remedy is effective and is protective of human health and the environment by controlling exposure to the subsurface and groundwater. After the draft UECA is complete, Chemours will submit that draft to WVDEP for review.

4.2.2 Monitored Natural Attenuation (MNA) with Hydraulic Containment and Wastewater Treatment

Groundwater Monitoring Program

In accordance with the FDRC, the purpose of the groundwater monitoring program is to "…demonstrate that the inward gradient is maintained, and that the contaminant mass is being reduced through natural attenuation." Note that at the time of the FDRC (2015), the natural attenuation focus was on chlorinated VOCs as there was (and currently remains) no evidence that PFAS are appreciably degraded through natural attenuation mechanisms. The groundwater monitoring program was submitted in March 2019 and approved by WVDEP in April 2020, and consists of two elements:

- Groundwater analytical monitoring
- Groundwater elevation measurements.

The purpose of the quarterly groundwater analytical monitoring program is to evaluate the changes in concentrations of PFOA and select VOCs.

The quarterly groundwater monitoring program was implemented in 2019 and continued in 2020. In the *2020 Routine Monitoring and Corrective Measures Assessment Report* (AECOM, 2021), Chemours recommended optimization for the Monitoring Program that included eliminating monitoring of MNA parameters and modifying the VOC and PFAS monitoring frequency from quarterly to semiannual for the next two years, with another program evaluation for optimization to be completed after the two years of semiannual monitoring. In addition, Chemours recommended that the groundwater elevation measurement portion of the program be modified from a quarterly frequency to a semiannual frequency for two years, again followed by another program evaluation for optimization at that point. These recommendations were approved on April 22, 2021, in an email communication from Kenan Cetin (WVDEP) and Andrew Hartten (Chemours) and were implemented in 2021.

In the *2021 Routine Monitoring and Corrective Measures Assessment Report* (AECOM, 2022), Chemours recommended continuing semiannual sampling for VOCs and PFAS for two more years to perform statistical trend analysis using the additional data and then evaluate the Monitoring Program for optimization. In the *2022 Routine Monitoring and Corrective Measures Assessment Report* (AECOM, 2023), Chemours reviewed current trends and recommended continuing with semiannual sampling for VOCs and PFAS for two more years, performing statistical trend analysis using the additional data, and then evaluating the Monitoring Program for optimization after the 2024 program has been implemented.

In the WVDEP November 2022 comment letter pertaining to the 2021 report, WVDEP requested that Chemours switch to Method 8327 for PFAS analysis. However, the PFAS sampling had already been completed for the 2022 semiannual events. Chemours then

proposed using EPA Method 1633 DRAFT, consistent with a request from EPA Region 3. WVDEP approved this proposed method change during a call with Chemours and AECOM on February 27, 2023. Therefore, beginning in 2023, samples were analyzed using EPA Method 1633 DRAFT.

Hydraulic Containment

The FDRC requires that Chemours "…maintain a groundwater monitoring program to demonstrate that the inward gradient is maintained and that the contaminant mass is being reduced through natural attenuation." The purpose in collecting groundwater elevation measurements and evaluating those data is to confirm that Chemours is maintaining hydraulic containment. To confirm hydraulic control of on-site groundwater, the groundwater monitoring program includes the collection and analysis of groundwater elevation data at select on-site wells. Specifically, measurements of groundwater elevation and river water elevation are collected for the following purposes:

- Evaluate the direction of groundwater flow in the alluvial aquifer.
- Evaluate any changes in the direction of groundwater flow.
- Confirm that site groundwater within the alluvial aquifer is not migrating off-site.
- Document continued hydraulic control.

In addition, as part of this requirement, the FDRC specifies that the Site continue production well pumping at a minimum rate of 4 million gallons per day to maintain hydraulic control of on-site alluvial aquifer groundwater. Refined groundwater flow modeling using the 2003 groundwater flow model (DuPont, 2003) was provided to WVDEP in the first quarter 2021 associated with the financial assurance cost estimate for the Site[22] as Attachment 2 (see Appendix I).

However, current process water needs require pumping of additional production wells as indicated in Section 5.2 of the *2022 Routine Monitoring and Corrective Measures Assessment Report* (AECOM, 2023). In 2022, the Site average pumping rate was 6 mgd.

[22] The updated Washington Works RCRA Corrective Action Financial Assurance estimate submitted electronically on July 22, 2021, by Andrew Hartten (Chemours) to WVDEP includes a PowerPoint presentation that provides the refined groundwater flow modeling results.

In the 2022 report (AECOM, 2023), Chemours recommended continuing with semiannual groundwater elevation measurements and then evaluating the program for optimization after the 2024 program has been implemented.

Process Water Treatment Via the Wastewater Treatment Plant

Some of the water discharged from process areas is treated via the Site biological WWTP, which is owned and operated by Chemours, before being discharged to the Ohio River via the outfalls. The Site biological WWTP consists of sedimentation, neutralization, biological activated sludge treatment, and clarification. This biological WWTP treats some of the wastewater from Chemours, and site tenants, and ultimately discharges through Outfall 005 to the Ohio River. Wastewater sent to the biological WWTP includes wastewater from Chemours' fluoropolymer manufacturing operations, which is pretreated via GAC but may contain PFAS, including HFPO-DA. In addition, the wastewater from New DuPont's operations may also contain PFAS.

In support of these NPDES outlets permit requirements, but unrelated to the CMIP, the Site also constructed a GAC treatment system to treat the Ranney Well water, prior to its use as process water. The GAC treatment system became operational in November 2021, and additional details are provided above in Section 3.4.

The continued treatment of captured groundwater portion of the selected remedy for the facility is functioning as detailed in the CMIP. No changes to the continued treatment of captured groundwater portion of the CMI have been recommended since the CMIP was implemented in 2019.

Drinking Water Granular Activated Carbon Treatment

The selected remedy for the Site requires that the water that is intended to be used as potable water for the Site be treated for PFOA and select VOCs until concentrations of groundwater are reduced to their respective MCLs. The Site operates the potable water GAC treatment system to comply with current drinking-water standards. Potable water produced in the treatment system is for on-site use only. The system is operated in accordance with SOPs, and treated water is routinely tested to confirm that drinking-water standards for PFOA and HFPO-DA are met. No changes to the continued treatment of captured groundwater portion of the CMI have been recommended since the CMIP was implemented in 2019.

4.2.3 Landfill Cap Operation, Maintenance and Monitoring

The RBL/ADP SWMUs were addressed via installation of an engineered cap system as an IRM under the RCRA permit (Section 4.1.3). The final element of the selected remedy is the continued inspection and maintenance of the RBL/ADPs engineered cap system. As indicated in the FDRC, the purpose of the maintenance and monitoring of the cap system is to "…maintain its effectiveness and protectiveness and to ensure the health and safety of site workers and to reduce the possibility of trespasser exposure to SWMU materials." Implementation consists of continuing the current inspection and maintenance plan.

The RBL/ADPs engineered cap system is in good condition and is performing as designed to ensure the health and safety of site workers and to reduce the possibility of trespasser exposure to SWMU materials. Quarterly site inspections will continue to be performed to document the condition of the landfill and to identify and manage any maintenance items that are required to ensure that the landfill is maintained in accordance with the original design. No changes were recommended by Chemours with

respect to the overall inspection and maintenance of the RBL/ADPs engineered cap system. This remedy is effective, and no changes are recommended for the inspection frequency. Any issues identified in the quarterly inspection are managed, as needed, in a timely manner. In the 2022 annual report, Chemours recommended that mowing of the RBL/ADPs engineered cap system be increased to twice per year, and that the Filtrex socks that were installed in the Second Quarter 2022 (2Q22) on five outfalls be changed on an annual basis.

4.3 Non-RCRA Corrective Measures

4.3.1 Off-Site Private and Public Drinking Water Treatment

In addition to the on-site PFAS abatement technologies installed over time at the Site to remove PFAS from production well water prior to use as process water and to reduce PFAS from waste streams generated during the fluoropolymer manufacturing, off-site private and public drinking water treatment began in early 2006.

Surveying and PFOA sampling of private water systems and PWSs in West Virginia and Ohio first began in 2001 and continued under various regulatory programs and legal orders. Surveying and sampling are ongoing under the Safe Drinking Water Act (SDWA) First Amendment to Order on Consent (FAOC), which was effective as of January 6, 2017, when EPA, DuPont, and Chemours agreed to amend the 2009 Consent Order in accordance with the terms and conditions contained in the FAOC.

The most recent 2009 Consent Order as Amended Quarterly Progress Report (QPR) titled *2023 Annual and Quarterly Progress Report No. 28 – 2009 Consent Order as Amended* (AECOM, 2024b) includes validated sampling results through December 12, 2023 for PFOA and other PFAS obtained for new drinking-water sources sampled, from monitoring of GAC treatment systems installed at private water systems and PWSs, and from PWS production wells, if sampled. As per the FAOC, monitoring for PFOA and treatment offers for wells with PFOA equal to or greater than the EPA Lifetime Health Advisory (EPA 2016 HA) value for PFOA of 0.07 micrograms per liter (µg/L) is being performed as part of the following:

- “Surveying and sampling requirements for private water systems pursuant to the 2009 Consent Order as Amended Paragraphs 42(a), 42(c), 42(d), and 42(g through k) and Exhibit B
- Surveying and sampling requirements for public water systems pursuant to the 2009 Consent Order as Amended Paragraphs 42(b through d) and 42(g through k) and Exhibit B
- Operation, maintenance, and monitoring requirements for private water systems pursuant to the 2009 Consent Order as Amended Paragraphs 42(e), 42(l) and 42(m) and Exhibit A
- Operation, maintenance, and monitoring requirements for public water systems pursuant to the 2009 Consent Order as Amended Paragraphs 42(f), 42(l) and 42(m) and Exhibit A”

The QPRs include tables, applicable footnotes, figures, and appendices that are updated as needed in each report.

Qualification for a treatment offer was based on exceeding the PFOA criterion specific to the individual program. Under the current program, the criterion used is the EPA 2016

HA of 0.07 µg/L. Three treatment options may be available for private drinking-water sources qualified for treatment. These include installation of a GAC treatment system, connection to a PWS (if practical), or permanent bottled water delivery. PWS connections and permanent bottled water delivery are considered alternative forms of treatment and are EPA approved alternatives. Temporary bottled water is offered as an interim measure for locations where GAC treatment systems are being installed and where PWS connections are being completed. Under the 2009 Consent Order as Amended, treatment is not offered for private drinking-water sources with PFOA less than or equal to the EPA 2016 HA of 0.07 µg/L. To date, drinking water treatment implemented at public water supplies consists of installation of GAC treatment systems.

As of December 12, 2023, the following statistics summarize the status of sampling and treatment, where required, for private and public drinking water supplies qualified for an offer of treatment since 2001:

- 356 Private Drinking Water Sources (wells and springs) had PFOA greater than 0.07 µg/L or above the treatment criterion at the time the source was sampled[23].
- One source has treatment in progress.
- 147 sources have had a GAC treatment system installed.
- 140 sources have been connected to a public water supply.
- 43 sources have bottled water provided.
- 25 sources have various other situations ongoing[24].
- Eight Public water supplies (including at the Site) had PFOA greater than 0.07 µg/L or above the treatment criterion at the time the source was sampled and 11 well fields have had GAC treatment system installed.
- One Transient Non-Community Water System has PFOA greater than 0.07 µg/L and has had a GAC treatment system installed.

Where Chemours has installed GAC systems at private and PWSs, these GAC systems have been included in ongoing operation, maintenance, and monitoring (OM&M) programs. OM&M for private GAC systems includes sampling prior to treatment (PT) water on an annual basis and treated water on a quarterly basis. Although there are two carbon filters in series for private GAC systems, treated water after the first filter is sampled during the quarterly OM&M events and when the concentration of PFOA in that water reaches 0.015 µg/L, a carbon changeout is performed. This sampling process ensures that resident's exposure to PFAS in drinking water is limited because of the presence of the second carbon filter, which acts as a polishing step in the treatment process. For PWS GAC systems, OM&M is performed on either a biweekly or monthly basis and includes sampling of PT water and treated water after the first and second filters. For PWS GAC systems, carbon change outs are performed as required by the individual PWS OM&M agreements. GAC system monitoring results are compiled in the QPRs that are submitted to EPA as required under the FAOC.

[23] Drinking water treatment has been offered under several programs since the mid-2000s. Qualification for a treatment offer was based on exceeding the PFOA criterion specific to the individual program, which may have been less than the current criteria of 0.07 µg/L.
[24] Table 7 in the quarterly progress reports provides details on the status of each of these drinking water sources.

Additional details pertaining to the private drinking water surveying and sampling program results and the public water supply sampling results are provided in the tables, footnotes, figures, and appendices provided in the *2023 Annual and Quarterly Progress Report No. 28 – 2009 Consent Order as Amended* (AECOM, 2024b). Evaluation of the geographic distribution and concentrations of PFAS detected above the reporting limits (RLs) in private and public water supplies is provided in Section 6.3.1.

4.4 Summary Observations on the RCRA Corrective Action, Corrective Measures Implementation and Non-RCRA Corrective Measures

Summary Observations on the RCRA CA, Corrective Measures Implementation and Non-RCRA Corrective Measures include the following:

- RCRA CA investigations, which began in the early 1990s, and ongoing regulatory driven programs (the SDWA surveying and PFAS sampling of private and PWS drinking water program, CMI and ACO activities) have generated PFAS results over time that show PFAS in on-site sources and in on-site environmental media.
- The FDRC was signed by WVDEP in November of 2017 and approved of the CMIP in October 2018. The selected remedial measures for the Site identified in the FDRC and in the approved CMIP are as follows:
  - Continued ICs.
  - MNA with continued production well pumping and hydraulic containment and with continued treatment of captured groundwater via the on-site WWTP.
  - Ex-situ treatment of waste process water at the WWTP.
  - Treatment of potable water from drinking water wells.
  - RBL/ADPs engineered cap inspection and maintenance.
- CMI began in January of 2019 and is ongoing.
- Surveying and PFAS sampling of private and PWS drinking water sources began in 2001 and is ongoing under the SDWA FAOC.
- As of December 12, 2023, 356 private drinking water sources (wells and springs) had PFOA greater than 0.07 µg/L or above the treatment criterion at the time the source was sampled and treatment was offered by Chemours. In addition, 11 GAC systems have been installed for eight PWSs by Chemours. Private and PWS with GAC systems installed are included in the Chemours ongoing OM&M program.

No data gaps were identified related to Site RCRA CA, corrective measures implementation and non-RCRA corrective action.

5.0 On-Site PFAS Conceptual Site Model

This section provides the updated On-Site CSM, including information on on-site PFAS sources, transport mechanisms, and migration pathways to on-site environmental media and data on the presence and distribution of PFAS in those media.

Figures 5-1 through 5-3 are three schematic cross sections through the Site, which depict the on-site PFAS sources, and the transport mechanisms and migration pathways from those sources to on-site environmental media. Only PFOA and HFPD-DA are depicted in these figures to represent historical and current operating conditions, although other PFAS are present. These on-site PFAS sources, transport mechanisms and migration pathways to on-site environmental media are also depicted in the flow chart included as Figure 5-4. Figure 5-4 depicts only the current PFAS sources and migration pathways. In the schematic cross sections, historical air emissions and water discharges are not depicted because they are not ongoing. However, historical PFAS in air emissions and historical wastes managed on-site have resulted in the presence of PFOA in Site soils and groundwater and are depicted in the flow chart in dashed boxes.

In the following subsections, the PFAS sources (Section 5.1), transport mechanisms and migration pathways (Section 5.2), and presence and distribution in environmental media on-site (Section 5.3) are described with the starting point for discussion purposes being the Washington Works fluoropolymer manufacturing processes. Numbers to the right of the symbols in Figure 5-4 are referenced in the subsections below, with the Washington Works fluoropolymer manufacturing processes being #1 in Figure 5-4.

5.1 PFAS Sources from the Washington Works Fluoropolymer Manufacturing Processes – Figure 5-4 #1

PFAS sources from the Washington Works fluoropolymer manufacturing process (Figure 5-4 #1 and depicted in Figures 5-1 through 5-3) include the following:

- #2: Historical PFAS in Air Emissions (~1950s-2013)
- #3: Historical On-Site Management of PFAS-bearing Solid Process Wastes via SWMUs and Landfills
- #4: Historical Discharges to the Ohio River
- #5: Process Solid Waste
- #6: Process Wastewater
- #7: Current PFAS in Air Emissions (2013-present)
- #8: PFAS from Leaks, Spills, etc.
- #9: PFAS in Equipment and Materials Handling

These PFAS sources are discussed in the subsections below.

5.1.1 Historical PFAS in Air Emissions (~1950s – 2013) – Figure 5-4 #2

PFOA and associated PFAS emitted from stacks in the fluoropolymer manufacturing area were predominantly particle-associated.

Historical PFOA and associated PFAS-bearing airborne emissions were transported with the wind and subject to removal via dry and wet deposition. Wet deposition occurs during rain and snow events when precipitation scavenges airborne PFAS and deposits it on surfaces. After deposition on surfaces, this PFAS can continue to migrate downward into soil via precipitation driven infiltration and can further migrate to groundwater via leaching from soil.

These air emissions were subjected to atmospheric dispersion and dilution in association with the local wind patterns. PFAS were distributed in ambient air at varying concentrations depending on a variety of process emission and meteorological factors. However, PFAS concentrations measured in residential wells and springs in both Ohio and West Virginia show that PFAS-containing air emissions have historically migrated from the Site in all directions to some extent (Section 6).

Although PFOA was completely phased out in 2013, the Site still discharges amounts of PFOA in air emissions due to the presence of PFAS in production well water used in the fluoropolymer manufacturing processes and due to the potential presence of PFOA in infrastructure associated with the fluoropolymer manufacturing process.

5.1.2 Historical On-Site Management of PFAS-bearing Process Wastes via SWMUs and Landfills – Figure 5-4 #3

From ~1950s through the complete transition to HFPO-DA as a replacement chemistry in 2013, PFOA was used in the fluoropolymer manufacturing processes as a surfactant and process wastes generated contained varying amounts of PFOA. As was discussed in Section 4.1.1, PFOA was found in wastes from the fluoropolymer manufacturing process that were managed at the Site in the former ADPs (Figure 2-8 and depicted schematically in Figure 5-2 as the capped RBL/ADPs landfill). PFOA was found during the VI to have migrated to soils and groundwater at the Site via precipitation while the units were in operation. The remediation of the ADPs and consolidation of those materials under the RBL/ADPs landfill cap was performed September 2011 until July 2012. This landfill cap is an engineered system with a 40-millimeter HDPE geomembrane liner to minimize water infiltration into the landfill materials. This liner is covered with a geo-composite drainage layer followed by 18 inches of general fill soil and a 6-inch topsoil layer[25]. This cap system presents a barrier to infiltrating precipitation, which drains via the geo-composite layer. With infiltration eliminated at the cap, the ability for precipitation to infiltrate through the landfill materials has been reduced.

In addition to the former ADPs, Chemours owns two landfills in West Virginia where fluoropolymer process wastes were managed by DuPont. These are the Dry Run Landfill and the Letart Landfill.

[25] *Riverbank Landfill IRM Complete Report*. URS Corporation. December 2013.

The Dry Run Landfill is located west of Lubeck, West Virginia, about eight miles southwest of the Site and Local Landfill. The Dry Run Landfill was originally permitted on October 26,1982 under Water Pollution Control Permit Number IWL-6282-82. The landfill was permitted under WV Solid Waste/NPDES Permit Number WV0076244 on January 12,1990. The current effective date of the permit is February 1, 2016, with Modification No. 5 on May 1, 2019. The permit renewal application was submitted June 10, 2020 and resubmitted February 11, 2021. The permit was then issued for public notice in March 2024 and issued as final on July 29, 2024. As per the permit, monthly, quarterly, or semiannual monitoring of PFAS occurs at several outlets and in monitoring wells. Waste was placed in the landfill from the Site beginning in 1986 and continued through 2006. The source of PFAS at Dry Run Landfill is thought to be the materials excavated from the ADPs in 1988. A leachate collection system was placed over existing landfilled materials in 1997-1998 and additional waste material was placed on top for the remaining life of the landfill. A GAC treatment system was installed in 2006 to remove PFOA discharging through the landfill's permitted outlet. A permanent engineered cap that included an impermeable geosynthetic cover and a vegetative cover was constructed in 2007.

The Letart Landfill is located north of Letart, West Virginia, in Mason County. The landfill was originally permitted under WVDNR Permit #3495. Letart Landfill was permitted under WV NPDES/Solid Waste Permit Number WV0076066 in the late 1990s. The current effective date of permit is September 1, 2015. A permit renewal application was submitted in January 2020, but a draft permit has not yet been received by Chemours. The permit requires quarterly or semiannual monitoring of PFOA in leachate, outlets, and monitoring wells. Waste was placed in the landfill from the Site from the 1960s through 1995 and included off-specification product, totes, and containers that were thought to be the source of PFOA in the landfill. The Letart Landfill was closed in 1995, and a geosynthetic membrane cap was installed in 2001. A leachate collection system was installed during the capping. A GAC treatment system was installed in 2006 to remove PFOA. Treated water is discharged via Outlet 002, which flows through a small ephemeral stream to the Ohio River.

5.1.3 Historical NPDES Discharges to the Ohio River – Figure 5-4 #4

Historically, the Site discharged PFAS-bearing process water and stormwater through outfalls (#4) to the Ohio River. These are depicted in Figure 5-4 as dashed boxes next to the outfalls but are not shown in the schematic cross sections. These discharges may have resulted in the presence of PFAS in the Ohio River water (#27A) and potentially in Ohio River sediments (#27B) as the river water that recharges the alluvial aquifer migrates through those sediment. The Ohio River water and river sediments are considered to be off-site environmental media, and the presence and distribution of PFAS in the Ohio River are discussed in Section 6.3.2. The Ohio River sediments have not been evaluated for the presence and distribution of PFOA nor any other PFAS.

5.1.4 Process Solid Waste – Figure 5-4 #5

Process solid waste from the fluoropolymer manufacturing processes (#5), which contains PFAS, is managed off-site via incineration or landfilling by a third party (#5A and depicted schematically in Figures 5-1 and 5-2). Only in situations where leaks or spills, or malfunctions of equipment that handle process solid wastes occur would process solid wastes be considered a source of PFAS that may migrate to on-site environmental media. These situations are discussed in Sections 5.1.7 and 5.1.8.

5.1.5 Process Water and Stormwater – Figure 5-4 #6 and #6A-D

Process wastewater from the fluoropolymer manufacturing processes (#6) is managed on-site and off-site in several different ways. Some process wastewater streams are managed off-site by a third party via incineration (#6A and Figure 5-1). Other process wastewater streams are treated on-site via GAC treatment (#6B and Figure 5-2), and treated wastewater is then discharged through the process water outfalls to the Ohio River (#27A and Figure 5-1). Spent carbon from the Ranney Well GAC treatment system is regenerated by the supplier although the regeneration process is unknown to Chemours and understanding that regeneration process is identified here as a data gap. Other process wastewater streams are treated on-site via the WWTP (#6C), and then discharged through process outfalls to the Ohio River (#27A). WWTP biosolids (#6D) are managed off-site along with the process solid wastes (#5A and Figure 5-1). Other process wastewater is discharged directly to process water outfalls (#5C) to the Ohio River (#27A).

A discussion of the Site process water outfalls and sources of waters to those outfalls was provided in Section 3.3. Note that during precipitation events, the process water outfalls also discharge stormwater. Figure 2-12 shows the basins and sub-catchments at the Site in which stormwater is generated during storm events that then discharges through process water outfalls and stormwater outfalls, which are shown in Figure 2-8 and depicted in Figures 5-1 and 5-2.

Stormwater at the Site (#16C) may contain PFAS that originate from on-site sources, including the following:

- #7: Air Emissions (2013-present)
- #8: Leaks, Spills, etc.
- #9: Equipment and Materials Handling

Stormwater migration pathways from these sources to stormwater outfalls are described in Section 5.2.2.

5.1.6 PFAS in Currently Air Emissions (2013 – Present) – Figure 5-4 #7

HFPO-DA and associated PFAS in air emissions currently can migrate to off-site environmental media (#10) in the same ways that PFOA and associated PFAS-bearing air emissions migrated to on-site environmental media (#11 and Figures 5-1 through 5-3). Migration pathways for PFAS-bearing air emissions to off-site environmental media are discussed below in Section 5.2.1. Migration pathways for PFAS-bearing air emissions to on-site environmental media are discussed below in Section 5.2.2.

5.1.7 PFAS from Leaks, Spills, Etc. – Figure 5-4 #8

PFAS have been released to Site environmental media from leaks and spills (#8 and depicted in Figures 5-1 and 5-2). There are several locations where process materials and solid wastes and wastewater are handled related to the fluoropolymer manufacturing. At these locations, leaks and/or spills can occur. Where at the Site a PFAS release happens and onto which type of surface (permeable to impermeable) it happens determine into which type of environmental media the PFAS migrate. Site best practices and spill management protocols prescribe how to manage PFAS releases from leaks and spills at the Site. Additional information on PFAS migration into on-site environmental media from leaks and spills is provided in Section 5.2.2.

5.1.8 PFAS in Equipment and Materials Handling – Figure 5-4 #9

As with leaks and spills, PFAS have been released to Site environmental media from equipment and materials handling (#9 and depicted in Figure 5-3) during fluoropolymer manufacturing process. There are several locations where equipment and materials handling related to the fluoropolymer manufacturing are managed. At these locations, leaks and/or spills can occur. As with leaks and/or spills of PFAS in solid waste or wastewater, where PFAS releases via leaks and/or spills from equipment and materials handling within the manufacturing processes happen determines in which direction the PFAS migrate into on-site environmental media (#11). An example of a known PFAS release from a materials handling location took place in a portion of the East Truck Pad (depicted in Figure 5-3) prior to 2018. In this part of the East Pad, roll-offs that contain filter cake from the Site's W9 treatment system were staged prior to off-site disposal. In 2018, soil was sampled in the vicinity of the roll-off staging area and was found to contain PFOA and HFPO-DA. In this case, PFOA and HFPO-DA from the spent filter cake was released to the permeable gravel pad. Section 5.3.3 (Roll-Off Staging Area Release Assessment) provides details of this investigation and the resulting actions to limit future releases from these roll-offs. The presence and distribution of PFOA and HFPO-DA from this release are provided in Section 5.3.3. As stated in the section above, the Site best practices and spill management protocols prescribe how to manage PFAS releases in these situations.

5.2 PFAS Migration Mechanisms and Transport Pathways

Migration mechanisms and transport pathways for PFAS in on-site sources to on-site media are depicted schematically in Figures 5-1 through 5-3 and shown in Figure 5-4. Because these migration mechanisms and transport pathways are depicted in all three schematic CSM figures, specific reference to the schematic CSM figures for each migration mechanism and transport pathway discussed below are not included, but references to the flow chart (Figure 5-4) are provided.

5.2.1 Pathways to Off-Site Environmental Media – Figure 5-4 #10

There are two historical PFOA and associated PFAS sources that have migrated to off-site environmental media, historical air emissions (~1950s to 2013) (#2), and historical discharges to the Ohio River (#4). There are also two current HFPO-DA and associated PFAS sources that also migrate to off-site environmental media, current air emissions (2013 to present) (#7), and current process and stormwater outfalls to the Ohio River, (#12 and #5C, respectively). Because PFOA is no longer used as a polymer processing aid, historical discharges of PFOA and associated PFAS in process and stormwater to Outfalls are shown in dashed boxes next to the current process water outfalls (#5C) and stormwater outfalls (#12). A detailed discussion of the transport mechanisms and migration pathways to off-site environmental media and the presence and distribution of PFAS in off-site environmental media from these current and historical sources is presented in Section 6.

5.2.2 Pathways to On-Site Environmental Media – Figure 5-4 #11

PFAS sources that can currently migrate to on-site environmental media include the following:

- #7: PFAS in Current Air Emissions (2013-present)

- #8: PFAS from Leaks, Spills, etc.
- #9: PFAS in Equipment and Materials Handling

Current air emissions containing HFPO-DA and related PFAS (#7) [and historical PFOA and related PFAS in air emissions (#2)] can migrate to on-site environmental media (#11) via dry deposition and/or wet deposition. During dry deposition PFAS-bearing air emissions may be deposited on impermeable surfaces, such as building roofs, and concrete or asphalt ground surfaces, as well as depositing on permeable gravels, vegetated or soil surfaces. Soils at the Site are likely to contain PFOA and associated from those historical air emissions that may continue to leach PFAS via precipitation to the underlying Site alluvial aquifer. Although used for a much shorter timeframe of just over ten years, HFPO-DA and associated PFAS in air emissions that follow these pathways to Site soil also results in PFAS concentrations that may continue to leach via precipitation to the underlying Site alluvial aquifer.

In addition to dry deposition, PFAS in air emissions (#2) can also migrate to on-site environmental media (#11) via wet deposition. Wet deposition occurs during rain and snow events when precipitation scavenges airborne PFAS and deposits it on surfaces. Alternatively, precipitation can mobilize PFAS deposited on impermeable surfaces (#13) and permeable surfaces (#14), which can ultimately migrate via additional precipitation (#15) to soils (#17) and subsurface soils (#19), and to the alluvial site aquifer (#21) or from surfaces to stormwater (#16) and to stormwater outfalls (#12).

There are several locations where solid wastes and wastewater are handled related to the fluoropolymer manufacturing processes. At these locations, leaks and/or spills (#8) can occur. In addition, releases of HFPO-DA and associated PFAS from equipment handling and process material management (#9) may occur. PFAS from the sources can migrate to impermeable surfaces (#13) or to permeable surfaces (#14).

Where leaks or spills of PFAS-bearing solid materials occur on impermeable surfaces, Site best practices are followed and the releases can typically be managed depending on the duration and magnitude of the release[26]. The same holds true for liquid releases bearing PFAS. However, the liquids may migrate in the direction of water flow either by gravity or via precipitation (#15). Water flow direction at the Site is a function of location at the Site. Some water flows directly into stormwater conveyances (#16) to stormwater outlets (#12) or to process water outlets (#6C). At other locations at the Site, water flows from impermeable surfaces (#13) to permeable surfaces (#14) and then to the shallow soils (#17) and further into the subsurface soil via precipitation (#19), likely eventually reaching the Site alluvial aquifer (#21) and migrating in groundwater in the direction of groundwater flow. Close to the alluvial terraces near the river, liquid releases containing PFAS may migrate via precipitation in the subsurface soils (#22) to Holocene sediment

[26] Releases of significant duration or magnitude that result in the identification of a new AOC or which could threaten human health and the environment, outside the facility, must be managed per the RCRA Hazardous Waste Permit WVD 045 875 291 requirements.

water zones (#23) and/or with additional precipitation to the underlying site alluvial aquifer (#21). The rate and direction of the movement of precipitation in the subsurface is variable due to several factors including the amount of precipitation, the different permeabilities of the lithologies encountered, and whether the lithologies are saturated or not.

In addition, stormwater conveyances throughout the Site (ditches, drains, stormwater pipes) discharges stormwater directly to the Ohio River (#27A) through stormwater outfalls (#12). However, at some locations at the Site, stormwater discharges to process water conveyances and discharges with process water through the outfalls (#5C) to the Ohio River (#27A). PFAS-bearing waters discharging through process or stormwater outfalls may also potentially migrate to on-site environmental media by way of leaks in infrastructure or when repairs are made to the piping infrastructure (#25). If releases do occur, these PFAS-bearing waters can migrate to underlying shallow or subsurface soils (#17 or #19) then to the Site alluvial aquifer (#21).

When PFAS-bearing process or stormwaters in process water and stormwater outfalls discharge to the Ohio River (#27A), these waters are migrating to off-site environmental media (#26), specifically to surface water in the Ohio River (#27A). Once in the river water, these discharges mix with the river water and flow downstream. Ohio River water may interact with river sediments. Ohio sediment (#27B) may potentially contain PFAS from PFAS-bearing process or stormwaters in process water and stormwater outfalls or overland flow of stormwater to the Ohio River. No sampling of Ohio River sediments has been completed, and the presence and distribution of PFAS are identified as a data gap (described in Section 6.3.3) as river sediments are included as an off-site environmental media. Ohio River water also recharges the Site alluvial aquifer (#21) because of the pumping of the various production wells and well fields at the Site (#28A to #28C) as shown in Figure 2-10.

Water extracted from production wells on the Site and from the Blennerhassett Island well field (#28D) is used for various purposes at the Site:

- Well 336 (#28A) is a production well in the East Well Field that is used for Site potable water. Water from this well is the feed to the Site potable water GAC treatment system (#29). Treated water is then piped throughout the Site for potable water use (#30). The distribution of PFAS in Well 336 and in treated water is presented below in Section 6.1.2.
- The Ranney Well (#28B) is a production well for which a GAC treatment system became operational in November 2021 to reduce the concentrations of PFAS in process water from the fluoropolymer manufacturing processes (#1). The distribution of PFAS in the Ranney Well prior to installation of the GAC treatment system and in GAC treated process water (#32) is presented in Section 6.1.2.
- Water from wells 331, 332, 333, 334, 335 and 337, which are in the East Well Field, the five wells in the west well field, the Gallery Well (#28C), and the Blennerhassett Island Well Field wells (#28D) are untreated prior to use at the Site. Waters from these production wells are used for process water (#33), for producing demineralized water (#34) and for non-contact and contact cooling water (#35) for the fluoropolymer manufacturing processes (#1). The distribution of PFAS in on-site production wells listed here is presented in Section 5.3.6.

5.3 PFAS in On-Site Environmental Media

Prior to approximately 2018, the majority of environmental media sampled on-site by DuPont, and then by Chemours, was only analyzed for the PFO anion (the entity detected by the analytical instrument) and reported as APFO and/or PFOA (the disassociated form of APFO in aqueous solutions). Beginning in 2018, Chemours began to analyze select samples of on-site and off-site environmental media (predominantly drinking water, groundwater, process water and stormwater) via various PFAS analyte lists and analytical methods, such as EPA Method 537, EPA Method 537.1, EPA Method 1633 DRAFT, and non-targeted analysis using liquid chromatography coupled to high resolution quadrupole time of flight mass spectrometry. Therefore, water PFAS data evaluated for this updated CSM are primarily the results finalized by Chemours within the past five years or less. However, for other non-water environmental media sampled only for PFOA (for example soil and air emissions), those data are included in this evaluation regardless of the results finalization date because these results capture snap shots in time of the presence and distribution of PFOA in those on-site environmental media during a timeframe when the Site began to implement PFAS abatement technologies.

5.3.1 PFOA In Historical Air Emissions

Air monitoring was conducted at the Site fence line from November 2003 to March 2004. Two sampling methods were used:

- Occupational Safety and Health Administration (OSHA) Versatile Sampling (OVS) tubes
- High-Volume Impactor samplers.

The purpose of the monitoring was to demonstrate monitoring methods and establish a baseline concentration for that time at the Site. Methods and results for this air sampling program were summarized in a 2006 publication, which was included in Appendix 5.3 of the Data Assessment Report (DuPont, 2008). Figure 5-6 reproduces information presented in that publication that are summarized below.

Six sampling events using OVS tubes were conducted over a ten-week period from November 2003 to January 2004. During each sampling event, one sample was taken at five locations along the fence line plus an additional sample was taken at a spot co-located near the sampling location predicted to have the highest concentration of PFOA (Figure 5-6). High volume sampling was conducted in March 2004 during a 72-hr time period at four of the same locations (1, 2, 3 and 5) used for the OVS sampling (Figure 5-6). Twenty-eight pairs of useable results were generated. Results from the high-volume sampling were used to calculate a particle size distribution and to determine ambient air concentrations at the fence line. A summary of ambient air OVS results is provided in Figure 5-6 and showed a range in OVS tube monitored PFOA concentration from less than 0.012 microgram per meter cubed ($\mu g/m^3$) to 0.9 $\mu g/m^3$. In addition, the OVS tube sampling showed that PFOA in air emissions was present in the particulate form and no material was detected in the vapor portion of the sampling tube. Sampling results from the OVS tubes and the high volume samplers were consistent in measuring the highest PFOA concentrations at Stations 2 and 3, which were located downwind of the prevailing wind direction.

A second air monitoring event was conducted from August to October 2005 and consisted of sampling ambient air (including particle size distributions) and rain at nine

locations for nine events. Because eight of the nine sampling locations were off-site (two in West Virginia and six in Ohio) and only one location was on the Site, the second air monitoring event and the results are presented in Section 6.3.6. However, it is noted here that during this second ambient air monitoring event, the highest concentrations of PFOA in the OVS tubes and in the high-volume samplers were observed at the on-site monitoring location during each of the nine monitoring events.

The results from these two ambient air sampling events show that PFOA was present in air emissions in the particulate form in the early to mid-2000s, was detected at several locations on the Site, and that PFOA in air emissions was a source to on-site surfaces and soils.

5.3.2 PFAS in Current Air Emissions

Extensive stack sampling data and reports for the Site were provided to EPA in the October 2020 CWA Section 308 Information Request Response, the May 2022 Toxic Substances Control Act (TSCA) Information Request Response, and the April 2023 TSCA Information Request Response.

5.3.3 PFOA and HFPO-DA in Soil

On-site soil was sampled and analyzed for PFOA during several investigations including the VI in 1991-1992, the RFI in 1996-1997, the on-site soil/grass investigation in 2005, and the release assessment for the Chestnut Tree Plantation and the East Field AOCs in 2013. In addition, in May of 2018, soils in the East Pad were sampled for PFOA and HFPO-DA as part of a release assessment. Results for these investigations are presented below.

VI and RFI Soils

As stated in Section 4.1.1, the ADPs consisted of three digestion ponds co-located within the western portion of the RBL that were used for the containment and treatment of aqueous waste from the fluoropolymer manufacturing process and were used through 1988. The ponds were of earthen construction, were approximately 6 feet deep, and had a combined estimated volume of 3 million gallons. There were no outfalls from the ponds. Consequently, the ponds were operated to not overflow. However, during the VI (DuPont, 1992), soil sampling in 1991 found evidence of releases of PFOA to soil near the RBL and ADPs. Table 5-1 provides the PFOA results for the soil samples collected during the VI. Locations of these sampling points can be found in Figure 5-7[27]. Concentrations of PFOA are highest in samples collected from the vicinity of the ADPs with a range in concentration from 1.13 to 97 milligrams per kilogram (mg/kg). In general, the VI soil results show lower concentrations with increasing depth below ground surface in both samples collected from the ADPs and the RBL. Soil samples collected from RBLS8 are the exception, where the sample collected from 35 to 39 feet bgs has a PFOA concentration similar to the 2 to 4 feet bgs sample (0.94 and 1.06 mg/kg, respectively) while the 3 to 5 feet bgs sample was below the detection limit of 0.4 mg/kg.

During the RFI for the Site, soil was sampled again near and within the ADPs and RBL SWMUs, as well as near the BG, both at the surface (0 to 2 feet) and at depth (2 to 22

[27] Some samples from the soil boring locations shown in this figure from the RFI were not analyzed for PFOA.

feet). The PFOA results for these soils sampled in 1998 are also provided in Table 5-1. Boring locations are provided in Figure 5-7.

The soil samples collected for the RFI show the same trend of decreasing PFOA concentration with increasing depth. In addition, higher concentrations were observed in the vicinity of the ADPs. The highest PFOA concentrations in soil, up to 46 mg/kg, were found at depths of greater than 8 feet bgs near the former ADPs. Soil results from 1998 in Table 5-1 show that 51 surface soil samples were collected at a depth interval of 0 to 2 feet bgs during the RFI. The range of PFOA measured in those samples was from non-detect (less than 0.025 mg/kg) to a maximum of 9.1 mg/kg. Of those 51 samples, 41 are non-detect or have concentrations of PFOA less than 0.047 mg/kg. The range of PFOA observed in the other ten samples, which were located in the vicinity of the ADPs, shows PFOA greater than 0.047 mg/kg.

Based on the concentrations of PFOA and select VOCs in soils (and groundwater) from the VI and RFI, DuPont completed an IRM study in 2007 to evaluate the possible remedial options for the RBL/ADPs SWMUs. An engineered cap system on the RBL slopes and over the ADPs with supplemental tie-ins to existing cover in the production area was ultimately recommended to mitigate potential risks posed by the RBL/ADPs SWMUs. However, prior to capping, consolidation of fill and waste materials identified on the Ohio River terrace to the existing landfill slopes was completed to reduce the footprint of the SWMUs, minimize the potential of erosion and minimize human or ecological contact with PFOA- and VOC-bearing SWMU materials. Construction activities were implemented from September 2011 to December 2012, and the *Riverbank Landfill IRM Completion Report* was submitted in December 2013.

On-Site Soil/Grass

The 2005 On-Site Grass, Root and Soil Sampling Study examined PFOA concentrations in vegetation and soil located at and within one foot of the ground surface in the vicinity of ambient air sampling Stations 2 and 3 as shown in Figure 5-6. This investigation involved coring soil to a depth of 12 inches and subdividing the core into various media fractions (grass, roots, soil, etc.) for analysis of various physical parameters such as pH, clay content, PFOA concentration, and total organic content.

Table 5-2 provides summary PFOA results at the top of the table by sample depth followed by results for each sample for each depth. Table 5-2 shows that the range in concentrations of PFOA in soil samples collected from the top foot of soil range from 0.0242 mg/kg to a maximum of 0.134 mg/kg. In addition, Table 5-2 shows that the 1- to 3-inch depth soil samples have lower maximum concentration of PFOA (0.0696 mg/kg) compared to the 0 to 1-inch and the 3 to 6-inch and 6- to 12-inch depth samples (0.108 mg/kg to 0.13 mg/kg).

Table 5-2 also provides the PFOA results for grass samples. Concentrations of PFOA in unwashed grass are higher than those for the washed grass, indicating that surface deposition of PFOA on grass does take place. PFOA results for washed grass in Table 5-2 indicate that in addition to PFOA being deposited on the surfaces of grass, the growing grass blades may also uptake PFOA.

Release Assessment for the Chestnut Tree Plantation and the East Field AOCs

In the third quarter of 2010, DuPont identified two new areas of concern (AOCs) at the Site where on-site disposal of PFOA-bearing sludge had occurred. Available information regarding the on-site disposal was summarized in a July 12, 2006 letter from Robert

Ritchey, Senior Environmental Control Consultant, DuPont, to Cliff Whyte, Assistant Director, WVDEP, as follows:

- "In 1996 approximately 139 tons of bio-sludge from the Washington Works wastewater treatment plant were land-farmed at the site's East Field. It is estimated that the amount of C-8 in this sludge was less than one pound.
- Washington Works sanitary treatment plant sludge was land-farmed at the onsite experimental chestnut tree plantation, a project of the plant employee's Wildlife Habitat Committee, in 1995 and 1996. No records could be found that would allow calculating how much C-8 would have been present in this material, but it is believed to be minor."

In June 2013, these two new AOCs were investigated. Background soil sampling took place on June 11, 2013. Surface soil (0 to 0.5 feet bgs) was sampled at six locations adjacent to the two AOCs and at three locations away from the two AOCs, which are all representative of site-specific background (Figure 5-8). Table 5-3 provides boring information (boring ID and geological logs), sample information, and PFOA results for the background soil samples. The PFOA results in background surficial soils range from 0.0055 mg/kg to 0.047 mg/kg, which are within the same order of magnitude as the RFI surficial soil samples.

Sampling activities at the East Field took place at the Site between June 10 and 12, 2013. At the East Field, ten locations were selected for soil sampling. Table 5-3 provides boring information (boring ID and geological logs), sample information, and PFOA results for the East Field AOC soil samples. The PFOA results for East Field surface and subsurface soils range from 0.0043 mg/kg to 0.071 mg/kg. In general, concentrations observed at the AOC were consistent with those observed in the site-specific background locations (0.0055 mg/kg to 0.047 mg/kg) with samples collected from one location with slightly higher PFOA concentrations (0.066 mg/kg and 0.071 mg/kg in RA0613-EF6).

Sampling activities at the Chestnut Tree Plantation also took place at the Site between June 10 and 12, 2013. At the Chestnut Tree Plantation, ten locations were selected for soil sampling. Table 5-3 provides boring information (boring ID and geological logs), sample information, and PFOA results. Ranges of PFOA results for the Chestnut Tree Plantation soil samples are of the same order of magnitude as soil samples from the East Field AOC. The PFOA results for Chestnut Tree Plantation soils range from 0.0083 mg/kg to 0.041 mg/kg. Surficial soils and subsurface soils contained similar PFOA concentrations. Concentrations observed at this AOC were consistent with those observed in the site-specific background locations (0.0055 mg/kg to 0.047 mg/kg).

The conclusions from this release assessment were that the results presented in the RA report show that PFOA concentrations within these two AOCs, in which land-farming of PFOA-bearing biosolids occurred, are essentially the same as in background locations at the Site. As a result, no releases to underlying soils are indicated from the land-farming activities. The 2013 data set is essentially in the same range as the data from 1998.

Roll-Off Staging Area Release Assessment

In May 2018, Chemours conducted soil sampling investigation activities at the Site's Roll-Off Staging Area at the East Truck Pad (Figure 5-9). A portion of the East Truck Pad area shown in Figure 5-9 has been used (and continues to be used) to stage roll-offs that contain filter cake from the Site's W-9 treatment system (Section 3.4). The filter cake contains HFPO-DA and lesser concentrations of PFOA because PFOA is no longer used in the fluoropolymer manufacturing processes but is still present due to its historical use in processing equipment and its current presence in groundwater on-site, which is used for process water. Releases from the roll-offs to the soil may have occurred over time. The objective of this investigation was to determine whether the soil in this portion of the East Truck Pad has been impacted by a release from the roll-offs.

On May 16, 2018, soil boring and soil sampling field activities were initiated at the Roll-Off Staging Area in the East Truck Pad. The on-site AECOM field sampler collected soil samples, within each core, at the following intervals:

- Shallow: 0.5 to 1.5 feet bgs
- Middle: 5 to 6 feet bgs
- Deep: 9 to 10 feet bgs

Table 5-4 provides the HFPO-DA and PFOA results for these soil samples. A review of Table 5-4 identified the following observations. With the exception of soil boring SB10, HFPO-DA and PFOA were detected in each of the shallow soil samples (0.5 to 1.5 feet bgs). The shallow soil samples containing the highest HFPO-DA and PFOA concentrations were detected at locations SB14 and SB15. At SB14, HFPO-DA and PFOA were detected at 1.9 mg/kg and 0.22 mg/kg, respectively. At SB15, HFPO-DA and PFOA were detected at 3.9 mg/kg and 0.064 mg/kg, respectively. For the middle soil samples (5.0 to 6.0 feet bgs), eight of the 17 middle soil samples were non-detect (less than 0.0013 mg/kg) for HFPO-DA and PFOA. Nine of the 17 middle soil samples detected at least one of the two constituents. The middle soil sample containing the highest constituent concentrations was collected from location SB16 where HFPO-DA and PFOA were detected at 0.074 mg/kg and 0.0082 mg/kg, respectively. These concentrations are at least a magnitude lower than the highest concentrations associated with the shallow soil samples. For the deep soil samples (9.0 to 10.0 feet bgs), 12 of the 17 deep soil samples were non-detect for HFPO-DA and PFOA (less than 0.0013 mg/kg). The remaining five deep soil samples had detectable HFPO-DA; however, PFOA was not detected. The five deep soil samples that had detectable HFPO-DA were all collected from borings located near the southern border of the study area (SB13, SB14, SB15, SB16, and SB17). The deep soil sample containing the highest concentration of HFPO-DA was collected from location SB15 with a concentration of 0.220 mg/kg.

The detections of PFOA in the May 2018 investigation soil samples at concentrations above the interpreted background concentrations from air emission in 1998 and 2013 (less than ~0.05 mg/kg) indicates that a release had likely occurred in the vicinity of SB14 and SB15. Because these were the first HFPO-DA analyses for soil samples and the Site had only been using HFPO-DA for fluoropolymer manufacturing processes since 2013, the fact that a wide range in HFPO-DA concentrations was observed supports that the highest concentrations indicate that a release from the roll-offs had occurred. Subsequently, a concrete pad was installed over the release area and a secondary

containment pad was constructed in the East Truck Pad to stage roll-offs that contain filter cake moving forward.

Summary of On-Site Soil Results

The soil results presented here show that PFOA was present at many locations around the Site, including upwind and far away from the manufacturing area. The concentrations that were in the less than 0.05 mg/kg range are interpreted to be from fluoropolymer manufacturing process air emissions. However, the East Pad HFPO-DA results and the results for PFOA at concentration greater than the range observed at the background locations, and select high PFOA results in the vicinity of the ADPs, also indicate that releases via leaks or spills have occurred at select locations at the Site including historical releases from the ADPs and releases from materials handling in the East Pad. At these locations, higher concentrations of PFOA can be found relative to the lower concentrations observed outside of these locations. HFPO-DA and other PFAS have not been analyzed in soils other than at the East Pad, and the presence and distribution of PFAS other than PFOA are unknown and are identified as a data gap in the On-Site CSM.

5.3.4 PFAS in Monitoring Wells

Alluvial aquifer monitoring wells on-site have been sampled for PFOA as early as the 1990s as part of the VI. Currently, groundwater monitoring for PFAS is conducted as part of the CMI for the Site (Section 4.2.). The quarterly groundwater monitoring program that includes 10 alluvial aquifer monitoring wells and two production wells was implemented in 2019 and continued in 2020. Subsequently, monitoring was shifted to semiannual and is ongoing. Initially, samples were analyzed for 16 PFAS; however, beginning in the first half of 2023, samples were analyzed for 40 PFAS. However, the available PFOA data is limited for the on-site fractured bedrock monitoring wells, and the presence and distribution of PFAS other than PFOA is unknown and is identified here as a data gap.

Because there have been multiple sampling events for PFAS in monitoring wells (as well as production wells, process water outfall and stormwater outfalls) and the Site is an active fluoropolymer manufacturing plant; data for these sampling points are presented in two ways:

- A table summary that provides a list of PFAS analyzed at each sampling location, the frequency of detections, the range of RLs and the range of detections for the time period covered in the data set. All data summarized in these tables can be found in Appendix J.
- A table that provides, in general but with a few exceptions as noted, the results for the most recently completed sampling event for PFAS and a figure that shows the PFAS results detected above the RLs for that sampling event for that environmental media on-site (e.g., groundwater monitoring and production wells).

Table 5-5 provides a summary of the quarterly and semiannual PFAS results from March 2019 through October 2023. This summary table provides a list of PFAS that have been analyzed in these samples, the number of times that the specific PFAS has been analyzed, and the number of times that the specific PFAS has been detected above the RLs. For each PFAS, the range in RLs is provided for PFAS not detected above the RLs. For each PFAS detected above the RLs, a count of the number of detections above the RLs is provided as well as the range in concentrations detected. The evaluation of

PFAS concentrations over time in select monitoring wells is identified as a data gap. Table 5-6 provides the results for PFAS in the second half 2023 sampling event.

The information summarized below and in other subsections is based on reviewing the maximum concentrations observed for PFAS in the monitoring wells that are presented in Table 5-5. However, it is important to note that the range in detections above the RLs is also provided and that in general, for PFAS with higher magnitudes of detection (i.e., PFOA and HFPO-DA but not limited to these two PFAS) the range in detections can be several orders of magnitude.

The presence and distribution of PFAS in monitoring wells vary depending on the location of the monitoring well and whether PFAS are screened in water in the sands, slits, and clays of the overbank deposits or in the sands and gravels of the underlying alluvial aquifer. M04-MW02, an overbank deposit well on the lower terrace in the vicinity of the former ADPs, in general shows the highest concentrations of PFAS and had the highest number of PFAS detected above the RLs. Alluvial aquifer wells located in the vicinity of the fluoropolymer manufacturing area, such as N05-MW01, P06-MW02, P08-MW01, have higher groundwater elevation measurements compared to S05-MW02 indicating that groundwater flows from those wells towards S05-MW02 and the Ranney Well (Figure 2-10 and groundwater elevation maps provided in Appendix C). Those three wells also show relatively high concentrations of PFAS and several PFAS detected. Monitoring wells located further away from fluorotelomer manufacturing areas and the former ADPs, in general have lower concentrations of PFAS (D08-MW01, E13-MW01, T13-MW01, and Z07-MW01) and fewer PFAS detected above the RLs. In general, Table 5-5 indicates that PFOA and HFPO-DA are present in the highest concentrations and frequently observed at an order of magnitude higher than other PFAS. Depending on location, PFHxA, PFHpA, perfluorobutanoic acid (PFBA), perfluoropentanoic acid (PFPA), and perfluorononanoic acid (PFNA) are generally measured at about an order of magnitude less than PFOA/HFPO-DA, and other PFAS observed are generally measured at an order of magnitude lower. However, exceptions to these generalizations also exist. For example, PFHxS, is observed at a maximum concentration of 730 ng/L in E13-MW01. Groundwater in this area of the Site flows from west to the east onto the Site from the adjacent former Sabic property. Perfluorodecanoic acid (PFDA) in N05-MW01 is observed at a maximum concentration of 1,700 ng/L and only PFOA is observed at a higher concentration. PFOS in AE11-MW01 is observed with a maximum concentration of 230 ng/L, which is the maximum concentration in the data set summarized here. PFOS is also not utilized in fluoropolymer manufacturing process. AE11-MW01 is located on the southern boundary of the Site next to the railroad tracks and DuPont Road (SR 892).

The general presence of PFAS in industrial articles of commerce (https://doi.org/10.1016/j.hazl.2023.100086) that may have been or are used at the Site such as lubricants, greases, paints, cleaning products and associated with the operation and maintenance of equipment, vehicles and railcars was identified as a data gap in Section 3.2.

Table 5-6 provides the PFAS results for the October 2023 sampling event and Figure 5-10 provides data post boxes for the PFAS detected above the RL in monitoring wells for that monitoring event. As was observed in summary Table 5-5, M04-MW02, a Holocene sediment water well, and the monitoring wells in the vicinity of the fluoropolymer manufacturing area in general has the highest detections of PFAS and a larger number of PFAS detected than monitoring wells located farther away. For the

other monitoring wells with lower RLs in general for the October 2023 sampling event (AE11-MW01, D08-MW01, and E13-MW01), PFAS concentrations are similar to the maximum concentration detected with a few exceptions. PFOA in T13-MW01 is 4,700 ng/L, lower than the maximum detected in that well of 12,000 ng/L.

The presence of PFAS other than PFOA over time in monitoring wells has not been evaluated, and it is identified here as a data gap. Chemours will be generating trend graphs for select PFAS over time in on-site monitoring wells and performing quantitative evaluation and analysis beginning with the second half 2024 monitoring well results when those results are available.

5.3.5 PFAS in Production Wells and the River Intake

The presence and distribution of PFAS in on-site production wells and the river intake are provided below. Ohio River water is directly used via a river water intake to supply process water for the manufacturing process. The Ohio River is considered to be an off-site environmental media; therefore, PFAS results for Ohio River water are presented in Section 6.3.2. However, because river water is used for process water, PFAS results for the river water intake are provided here.

Table 5-7 provides a summary of the PFAS results for production wells sampled between September 2018 through October 2023. This summary table provides a list of PFAS that have been analyzed in these samples, the number of times that the specific PFAS has been analyzed, and the number of times that the specific PFAS has been detected above the RLs. For each PFAS, the range in RLs is provided for PFAS not detected above the RLs. For each PFAS detected above the RLs, a count of the number of detections above the RLs is provided as well as the range in concentrations detected. The evaluation of PFAS concentrations over time in select production wells is identified as a data gap. Figure 5-10 and Table 5-8 provides the PFAS in production wells for the October 2023 sampling event. In addition, PFAS results for the East Well Field Header, which was sampled in December 2023 and for which the results were finalized in January 2023, are also included in Table 5-8 as these are the first set of PFAS results for this location. The East Well Field Header sample represents combined production water from the East Field wells operating at the time of sampling, which is used as water for the fluoropolymer manufacturing process. Table 5-9 provides a summary of the PFAS results for the river intake between September 2018 through October 2023. Table 5-10 provides the PFAS in the river intake for the October 2023 sampling event. Detections above the RLs also provided on Figure 5-11.

As with monitoring wells at the Site, presence and distribution of PFAS in the production wells vary with location as can be seen in Table 5-8. Overall, Tables 5-7 and 5-8 indicate that PFOA and HFPO-DA are present in the highest concentrations and are frequently observed at an order of magnitude higher than other PFAS. Depending on location, PFHxA, PFHpA, PFBA, PFDA, PFPA, and/or PFNA are generally measured at about an order of magnitude less than PFOA/HFPO-DA, and other PFAS observed are generally measured at an order of magnitude lower than that. In general, wells located closer to the fluoropolymer manufacturing process area, such as the Ranney Well, have higher concentrations and more PFAS detected. Wells within the East Field in general, have lower concentrations and fewer detections of PFAS, although even within the well field concentrations and detection vary. Concentrations of PFAS detected in AO08-PW01 and AQ09-PW01 are similar, whereas AX13-PW01 is located at the far eastern edge of the Site and has much lower concentrations of PFAS.

The West Well Field Header and the East Well Field Header represent the combined water from production wells pumping at the time of the sample collection from each of these two well fields. The summary of West Well Field Header in Table 5-7 shows PFOA and HFPO-Da are the highest maximum concentrations, with PFHxA, PFHpA, and PFPA present around an order of magnitude lower than PFOA, with several other PFAS present another order of magnitude lower. It is notable that PFHxS is present in the West Well Field Header at a maximum concentration of 270 ng/L. Table 5-8 and Figure 5-10 show that for the October 2023 sampling event the PFAS results are similar to the maximums shown in the summary table with PFOA detected at the highest concentration, HFPO-DA and PFHxS are an order of magnitude lower and ten other PFAS observed another order of magnitude lower compared to HFPO-DA and PFHxS. Twenty-seven PFAS were not detected above the RLs shown.

For the East Well Header, Table 5-8 and Figure 5-10 show that in December 2023, of the 40 PFAS analyzed, 30 were not detected above the RLs shown. PFOA and HFPO-DA were measured at the highest concentrations at 510 and 590 ng/L. Eight other PFAS were detected above the RLs with the maximum concentration being 22 ng/L. Because only one sampling event was conducted for the East Well Field Header, additional monitoring to understand the presence and distribution of PFAS over time is identified as a data gap in the On-Site CSM.

.

These other sources may be related to the general presence of PFAS in industrial articles of commerce that may have been or are used at the Site and/or are possibly coming from off-site PFAS sources and this was identified as a data gap in Section 3.Table 5-9 provides a summary of the PFAS results for the river intake sampled between September 2019 through October 2023. This summary table provides a list of PFAS that have been analyzed in these samples, the number of times that specific PFAS has been analyzed, and the number of times that the specific PFAS has been detected above the RLs. For each PFAS, the range in RLs is provided for PFAS not detected above the RLs. For each PFAS detected above the RLs, a count of the number of detections above the RLs is provided as well as the range in concentrations detected. Table 5-10 provides the PFAS in the river intake for the October 2023 sampling event. Detections above the RLs also provided on Figure 5-10.

As with other on-site environmental media, the summary data for September 2018 through October 2023 in Table 5-9 show that the presence of PFOA and HFPO-DA is at the highest concentrations in river intake water, but that the ranges on these two PFAS observed are lower than in other on-site environmental media at maximum

concentrations of 210 ng/L and 89 ng/L, respectively. Six other PFAS were detected but at much lower concentrations with maximum concentrations of between 1.8 ng/L and 7.5 ng/L. Table 5-10 shows that in the October 2023 sampling event, four PFAS were detected above the RL and that the range in concentrations detected for these PFAS was 2.2 to 4.8 ng/L.

5.3.6 PFAS in Outfalls

PFAS in Process Outfalls

The Site's previous NPDES permit (effective September 3, 2003) included monitoring requirements for PFOA; the current permit (effective September 1, 2018) includes numeric limits for the discharge of PFOA and HFPO-DA. However, Modification No. 3, effective in the second quarter of 2019, requires additional outfalls be sampled for 18 PFAS. In addition, Chemours performed sampling events in August and September of 2018 and analyzed for a list of 46 PFAS. Beginning in November 2019, process water and stormwater outfall samples were analyzed for the 40 PFAS in EPA Method 1633 DRAFT.

Table 5-11 provides a summary of the PFAS results for process outfalls between August 2018 through December 2023. This summary table provides a list of PFAS that have been analyzed in these samples, the number of times that the specific PFAS has been analyzed, and the number of times that the specific PFAS has been detected above the RLs. For each PFAS, the range in RLs is provided for PFAS not detected above the RLs. For each PFAS detected above the RLs, a count of the number of detections above the RLs is provided as well as the range in concentrations detected. The further evaluation of PFAS concentrations over time in select process outfalls is identified as a data gap. Table 5-12 provides the results for PFAS for the December 2023 sampling event and Figure 5-11 data post for detected PFAS.

Table 5-11 shows that PFOA and HFPO-DA have the highest maximum PFAS concentrations detected in the process water outfalls. As with groundwater, there are another 5 or so PFAS detected one or two orders of magnitude lower in concentration compared to the PFOA and HFPO-DA. Depending on location, these PFAS can include PFHxA, PFHpA, PFBA, and PFPA. Present at another order of magnitude lower than that set of PFAS is a third set and again depending on location may include PFNA, perfluorododecanoic acid (PFDoA), PFBS, and PFOS. However, as with the groundwater PFAS results, there are some locations where a specific PFAS is present at a relatively higher concentration, outside of the generalizations made above. For example, in Outfall 005, the maximum concentration of PFHxA (4,270 ng/L) is two orders of magnitude higher that the PFHpA (69 ng/L), and in Outfall 007, the maximum concentration of PFHxA (1,800 ng/L) is one order of magnitude higher that the PFHpA (170 ng/L) when typically these two PFAS are present at similar concentrations.

Table 5-12 and Figure 5-11 show that, for the December 2023 sampling event, PFOA and HFPO-DA or PFOA or HFPO-DA (depending on the outfall) are present at one or two orders of magnitude higher than the next highest concentration five or six PFAS and that there is another set of PFAS detected at an order of magnitude lower. Compared to the summary maximums for PFOA and HFPO-DA in Table 5-11, the December concentrations are in general an order or two of magnitude lower. This holds true for the "mid-range" PFAS concentrations in the summary tables as well (Outfall 007 PFHpA maximum concentration of 170 ng/L in Table 5-11 and a December 2023 concentration

of 22 ng/L and see Outfall 001 PFOS maximum concentration of 170 ng/L in Table 5-11 and a December 2023 concentration of 18.1 ng/L.

Variability between outfalls in Tables 5-11 and 5-12 also reflects that different manufacturing processes discharge to different outfalls and various abatement technologies have been installed both for some process water sources prior to use (Ranney Well GAC treatment system) and some wastewater prior to discharge (W-9). In addition, because this is an active manufacturing plant, other factors (such as shut downs, line breaks, etc.) also are likely responsible for the variability of PFAS results observed. In addition, while there are outfalls on the Site that manage stormwater only (see subsection directly below), stormwater is also discharged through some of the process water outfalls. Figure 2-11 provides the basins and catchment areas at the Site as well as the discharge point to the Ohio River for process outfalls and stormwater outfalls.

PFAS in Stormwater Outfalls

Table 5-13 provides a summary of the PFAS results for stormwater outfalls between September 2018 through October 2023. This summary table provides a list of PFAS that have been analyzed in these samples, the number of times that the specific PFAS has been analyzed, and the number of times that the specific PFAS has been detected above the RLs. For each PFAS, the range in RLs is provided for PFAS not detected above the RLs. For each PFAS detected above the RLs, a count of the number of detections above the RLs is provided as well as the range in concentrations detected. The summary includes the PFAS analyzed, then for each PFAS the number of results, the frequency of detections above the RLs, the range in concentration, and the median detection. The evaluation of PFAS concentrations over time in select stormwater outfalls is identified as a data gap. Figure 5-12 and Table 5-14 provide the results for PFAS for the October 2023 sampling event.

Stormwater outfalls at the Site flow during precipitation events, but flow is variable at the individual outfalls due to the size and duration of the event and the respective drainage area. As stated above, and shown in Figure 2-11, location on the Site and related manufacturing operation in the vicinity influence the PFAS concentration observed in each stormwater outfall. Precipitation mobilizes PFAS deposited on the surfaces. How much stormwater and from where it comes from on the Site can influence the concentrations of PFAS measured. The concentrations of PFAS coming through an outfall can also be variable depending on whether or not the “first flush” of water is sampled, or if the sample is collected from later in the event. Given these complexities, Table 5-13 shows some similar observations on the maximum concentrations as were made with groundwater and process water outlets. PFOA and HFPO-DA, in general, have the highest maximum concentrations that are an order of magnitude to two above a second set of PFAS, which are an order of magnitude higher in concentration than a handful (3-6 depending on location) of PFAS in the low to single digit ng/L range. This observation is seen on Outfalls 30 through 36. However, for these outfalls, PFPA in general appears to have a maximum concentration similar to PFOA at several locations. In addition, Outfalls 011, 022, 023 and 025 all have overall relatively lower concentrations compared to Outfalls 30 through 36 with the maximum HFPO-DA ranging from 0.8 to 0.43 ng/L. The drainage basins for Outfalls 030 through 036 and 016 and 019 are adjacent to the Ohio River, collect water from paved surfaces that are close to and downwind from the fluoropolymer manufacturing areas. Outfalls 022, 023 and 025 are located on the southwestern side of the Site, away from the fluoropolymer manufacturing areas , and are mostly soil surfaces with no impermeable surfaces.

Outfall 011 drainage basin includes the part of the East Pad where the Roll-Off Staging Area release of PFOA and HFPO-DA occurred.

Table 5-14 and Figure 5-12 present the results of the October 2023 sampling event with the exception of Outfall 019, which was not sampled at that time. Data for that outfall are from May 2020, the most recent set of results and for which PFAS were analyzed instead of just PFOA and HFPO-DA. These data show essentially the same observations, which are that stormwater outfalls along the river have relatively higher concentrations compared to those located in the southwest corner of the Site.

5.3.7 Non-Targeted Analysis PFAS Results for On-Site Environmental Media

In addition to the PFAS results discussed for on-site environmental media presented in Section 5.3.1 through 5.3.6, which show that PFOA and HFPO-DA are the primary PFAS detected in on-site environmental media, Chemours collected samples from process water outfalls, production wells and one outlet from the Local Landfill, which discharges to Outfall 001, and performed non targeted analysis of PFAS (Chemours, 2023). The purpose of the non-targeted analysis was to screen for unknown PFAS present in these samples with detection limits in the 2 to 20 parts per billion (ppb) range compared to other targeted methods with detection limits in the 1 to 10 ng/L range.

The results of the non-targeted analysis detected the presence of five PFAS in the data set, four of which were detected in targeted methods (such as EPA Method 537, EPA Method 537.1, EPA Method 1633 DRAFT) and include PFOA, HFPO-DA, PFHxA and PFHpA. The fifth PFAS detected in the non-targeted analysis is perfluoropropionic acid (PFPrA), which is not included in the targeted method utilized commonly.

As indicated in Section 3.4, EPA issued an ACO under Section 309(a) of the Clean Water Act, 33 U.S.C. § 1319(a) to Chemours on April 5, 2023. Section III.44. of that ACO requires Chemours to implement the Sampling Plan (Exhibit 3 of the Order) to characterize the nature of the stormwater runoff and effluent wastewater leaving the Site by conducting specified PFAS sampling to identify and quantify PFAS discharges at each permitted Outlet[28] using draft EPA Methods 1621 (for absorbable organic fluorine) and 1633, total oxidizable precursor assay, and non-targeted analysis. In August 2024, Chemours submitted the report that contained the results for the stormwater runoff and effluent wastewater sampling event (see Appendix G). The results of that report showed the following:

- For the DRAFT EPA 1633 results, the new data presented show the same trends in concentrations discussed above in Section 5.3.6 with HFPO-DA and PFOA present typically at an order of magnitude higher than a second set of three to four PFAS, which vary depending on location at the Site and which are present at an order of magnitude above a third set of three to four PFAS, which are present at low ng/L concentrations.
- Notably, the DRAFT EPA 1633 results show sulfonate PFAS, PFOS, PFHxS, PFBS are present at very low to less than the reporting limit concentrations in this data set.
- For the TOP assay results, comparing the “Pre” and “Post” sample pair results, most of the “Post” results show lower concentrations than the “Pre,” which

[28] The ACO uses the term “Outlet” instead of “Outfall.” The numbering convention of “Outlets” matches that of the “Outfalls.”

indicates that there are no precursors present in the Site process water effluent and stormwater samples.

- For the NTA results, only one of the 20 samples, a stormwater sample collected at Outlet 016, showed the presence of suspect analytes and only one suspect analyte was identified. Nineteen of the 20 process water effluent and stormwater outlet samples were shown to have no non-targeted compounds identified, which indicated that there are no unknown PFAS or precursors present in these samples at the level of detection for the method.
- Because the AOF method is relatively new, Chemours declines to make observations on this data set.

5.4 On-Site PFAS Conceptual Site Model Summary and Data Gaps

The updated CSM for the Site presented here shows that PFAS historically migrated and currently migrate from the Site fluoropolymer manufacturing process via air emissions and water discharges to on-site environmental media. From the 1950s through 2013, PFOA was used as a processing aid for the fluoropolymer manufacturing at the Site. On-site environmental media sampled through 2013 were only analyzed for PFOA and although the presence of a suite of PFAS associated with the use of PFOA as the processing aid was not analyzed for, it is now assumed to have existed based on the presence of various PFAS in on-site environmental media. After 2013, HFPO-DA was used as a replacement chemistry for PFOA and continues to be used.

Historical (prior to 2013) air emissions and discharges to the Ohio River have resulted in the presence of PFOA and the associated suite of PFAS in on-site environmental media. Current (after 2013 to the present) air emissions and discharges to the Ohio River have and continue to result in the presence of HFPO-DA and the associated suite of PFAS in on-site environmental media. PFAS in air emissions can migrate to on-site surfaces and via precipitation to stormwater then to soil and then to groundwater, or to on-site surfaces and via precipitation to stormwater and to the river water. PFAS in process water and stormwater outfalls discharge to river water and river water recharges the Site groundwater. Site groundwater and river water are used as process water for the fluoropolymer manufacturing processes at the Site.

The remediation of the ADPs and consolidation of those materials under the RBL/ADPs landfill cap was performed September 2011 until July 2012. This landfill cap is an engineered system with a 40-millimeter HDPE geomembrane liner to minimize water infiltration into the landfill materials. This liner is covered with a geo-composite drainage layer followed by 18 inches of general fill soil and a 6-inch topsoil layer[29]. This cap system presents a barrier to infiltrating precipitation, which drains via the geo-composite layer. With infiltration eliminated at the cap, the ability for precipitation to infiltrate through the landfill materials has been reduced. In addition, abatement technologies installed, such as the Ranney

[29] *Riverbank Landfill IRM Complete Report*. URS Corporation. December 2013.

The PFAS data presented in Section 5.3.1 through 5.3.6 show that there are many PFAS that have been analyzed in on-site media that are not detected above the RLs. The distribution of PFAS in on-site environmental media also show that PFOA and HFPO-DA are the primary PFAS detected above the RLs in on-site environmental media and are present at the highest concentration compared to other PFAS. In general (but variable depending on sample location and environmental media), there are also approximately five to ten other PFAS detected at concentrations an order of magnitude or two lower than PFOA and HFPO-DA. Depending on sample location and environmental media, there are typically another five PFAS in on-site environmental media present at two to several orders of magnitude lower than the PFOA and HFPO-DA concentrations. Further, non-targeted analysis results show that only one unknown PFAS, PFPrA, was identified above the 2 to 20 ppb RLs that is not included in routine targeted PFAS analysis methods.

While the information presented in this Section shows the framework for the on-site PFAS sources and the transport mechanisms and migration pathways from those sources to on-site environmental media, and provides what is known on the presence and distribution of PFAS in on-site environmental media, this update of the On-Site CSM has revealed the following data gaps for on-site environmental media:

- Spent carbon from the GAC treatment system is regenerated by the supplier although the regeneration process is unknown to Chemours, and the specific regeneration process is identified here as a data gap.
- HFPO-DA and other PFAS have not been analyzed for in soils other than at the East Pad for the release assessment. Therefore, the presence and distribution of PFAS other than PFOA in Site soil are unknown and are identified as a data gap in the On-Site CSM.
- The presence and distribution of PFAS, other than limited results for PFOA, in the fractured bedrock monitoring wells is unknown and is identified here as a data gap.
- The evaluation of PFAS concentrations over time in select monitoring wells, production wells, and process and stormwater outfalls is identified here as a data gap.
- Blennerhassett Island production wells are also used for process water at the Site. The presence and distribution of PFAS other than PFOA in process water from the Blennerhassett Island production wells have not been determined and this is identified as a data gap in the On-Site CSM.
- Because only one sampling event was conducted for the East Well Field Header, additional monitoring to understand the presence and distribution of PFAS over time is identified as a data gap in the On-Site CSM.

Activities to be conducted to fill these data gaps will be proposed in the Sampling and Analysis Work Plan to be submitted within 90 calendar days of EPA's approval of this updated CSM as required by Section V.48 of the RCRA 3013 Order.

It is important to note that there are several ongoing on-site regulatory-driven PFAS monitoring programs that include sampling of monitoring wells, production wells, and process water and stormwater outfalls (i.e., the CMI and ACO). As new PFAS results are finalized for these programs, those data will be evaluated and used to continue to enhance and improve the On-Site CSM.

Other than the data gaps identified above, the information presented in Section 5 documents what is currently known regarding the presence and distribution of PFAS in on-site PFAS sources and the transport mechanisms and migration pathways from those sources to on-site environmental media.

6.0 Off-Site Conceptual Site Model

This section provides the updated Off-Site CSM, including information on off-site PFAS sources, transport mechanisms, and migration pathways to off-site environmental media and data confirming the presence and distribution of PFAS in those media.

Figure 6-1 presents a schematic cross section, which depicts the on-site PFAS sources and migration pathways to off-site environmental media. These on-site PFAS sources and migration pathways to off-site environmental media are also shown in the flowchart included as Figure 6-2. Figure 6-1 depicts the current PFAS sources and migration pathways (see Section 3.2 for a discussion of the terms “historical” and “current” and their use in this off-site CSM when referencing PFAS in emissions and discharges). However, PFAS in air emissions and in historical wastes managed on-site have resulted in the presence of PFAS in environmental media off-site and are depicted in the flow chart in dashed boxes in Figure 6-2. The current PFAS sources in water discharges and air emissions are not grouped together because PFOA was initially used in fluoropolymer manufacturing and then was replaced by HFPO-DA by 2013.

In Section 6.1, the on-site PFAS sources are described with the starting point, for discussion purposes, being the Washington Works fluoropolymer manufacturing processes. Numbers to the right of the symbols in the flow chart (Figure 6-2) are referenced in the subsections below, with the Washington Works fluoropolymer manufacturing processes being #1 in Figure 6-2. In Section 6.2, transport mechanisms and migration pathways to off-site environmental media are discussed. In Section 6.3, PFAS presence and distribution within off-site environmental media are provided.

6.1 PFAS Sources from the Washington Works Fluoropolymer Manufacturing Processes – Figure 6-2 #1

There are two historical migration routes from the fluoropolymer manufacturing processes (#1) to off-site environmental media (#6 and #7): air transport via historical emissions (#2) and water transport via historical stormwater outfalls (#3A) and process water outfalls (#3B), which discharged to the Ohio River from the 1950s through 2013. There are two current (after 2013) PFAS migration routes to off-site environmental media (Figure 6-2), air transport of HFPO-DA and associated PFAS via air emissions (#4), and water transport via stormwater and process water outfalls to the Ohio River (#5A and #5B).

6.1.1 Historical and Current Air Emissions – Figure 6-2 #2 and #4

Historical air emissions (#2) have been deposited on environmental media off-site (#6). PFOA and associated PFAS were emitted from the process stacks located in the fluoropolymer manufacturing areas of the Site. A discussion of the air emissions was provided in Section 5.1.1. The wind rose provided in Figure 5-5 and PFOA concentrations measured in residential wells and springs in Ohio and West Virginia show that PFOA-containing air emissions have historically migrated from the Site in all directions to some extent but wind flow was focused to the northeast during that timeframe. Deposition of PFOA and associated PFAS from historical air emissions and HFPO-DA and associated PFAS from current air emissions (#4) are the primary PFAS transport pathway to off-site environmental media.

6.1.2 Historical and Current NPDES Water Discharges to the Ohio River – Figure 6-2 #3A, #3B, #5A, and #5B

PFOA and associated PFAS in historical stormwater outfalls (#3A) and process water outfalls (#3B) and HFPO-DA and associated PFAS in current stormwater outfalls (#5A) and process water outfalls (#5B) have discharged and continue to discharge to the Ohio River.

In areas downstream from the Site and adjacent to the Ohio River, PFAS in off-site environmental media come from both the historical and current PFAS discharge via the outfalls and the historical and current PFAS-bearing air emissions. Groundwater pumped from the alluvial aquifers located adjacent to the river (#10) is used as drinking water (#16) as depicted in Figure 6-2.

6.2 PFAS Transport Mechanisms and Migration Pathways to Off-Site Environmental Media

The PFAS transport mechanisms and migration pathways discussed below are depicted schematically in Figure 6-2. The same migration pathways for historical and current PFAS-bearing air emissions to on-site media exist for these emissions to off-site environmental media. Historical air emissions were, and current air emissions are, deposited on permeable surfaces (#8), impermeable surfaces (#9) and surface water bodies such as the Ohio River (#10). If the depositional surface was the Ohio River, historical PFOA and associated PFAS that is in the river water, mixed with river water and migrated downstream from the Site or partitioned into river sediments. For off-site permeable surfaces (#8) such as lawns or gravel areas, PFAS migrated with precipitation (#17) downward via precipitation into the soil and subsurface soil and ultimately to groundwater (#11 through #16), migrating wherever groundwater flows. Alternatively, PFAS may have migrated in stormwater (#11) and/or soil (#12) via runoff or to the Ohio River (#10). For impermeable surfaces (#9) such as roofs and driveways, PFAS migrated (#18) with stormwater during precipitation events, wherever stormwater migrated, which was likely to permeable surfaces (#11 through 16) in rural areas.

PFAS from historical and current outfalls discharged and discharge to the Ohio River (#10) where it mixed and continues to mix with river water and migrates downstream from the Site or potentially present in river sediments as described further below as a data gap in Section 6.3.3. Regional groundwater supplies are typically obtained from the Ohio River alluvial terrace deposits (#16). The saturated portion of the highly permeable sediments of the alluvial terraces along the Ohio River comprise the principal regional aquifer for water supply purposes and supplies several of West Virginia's and Ohio's largest public water supply systems. The pumping of production wells within the alluvial terraces in Ohio and West Virginia next to the Ohio River induces river water to recharge the alluvial aquifer (#16) as depicted in Figure 6-1 and shown in Figure 2-10. The potential presence and distribution of PFAS in Ohio River sediment downstream of the outfalls are unknown and is identified as a data gap in Section 6.3.3. In the vicinity of the Site, Ohio River water may interact with river sediments because of the pumping of the various production wells and well fields at the Site.

Drinking water sources [private (#19) and public (#20)] that contain PFOA greater than the EPA 2016 Health Advisory (HA) of 0.07 ug/L (or 70 ng/L) are offered drinking water treatment by Chemours; whereas, treatment is not offered for drinking water sources that have less PFOA than the EPA 2016 HA (#21). PWSs are provided with GAC

treatment systems that typically are installed at PWS well fields (#22). Private drinking water can be treated as follows:

- Installing GAC treatment systems (#22) or
- By connection to a PWS with a GAC system or to a PWS with PFOA less than the EPA HA (#23) or
- By providing permanent bottled water (#24).

However, there are some situations where private drinking water wells do not have treatment for a number of different types of reasons, such as the well owner declined the Chemours treatment offer or is not responsive to the treatment offer (#25). Section 4.4.3 provided a statistical summary of those programs. Quarterly progress reports are submitted on an ongoing basis and are comprehensive.

6.3 PFAS in Off-Site Environmental Media

On November 3, 2005, a Memorandum of Understanding (MOU) was entered into between the EPA and DuPont for a PFOA Site-Related Environmental Assessment Program. The Charge of the MOU is as follows:

> *"Are current PFOA environmental releases and sources of those environmental releases from the Site and the presence of PFOA in environmental media on and around the Site sufficiently understood so that pathways of migration and exposure to PFOA associated with that Site are adequately characterized and assessed on a screening level basis?"*

As part of the investigations completed under the MOU, PFOA was monitored in several types of environmental media between 2002 and 2011. Information presented in this section includes the following:

- Section 6.3.1 PFAS in Off-Site Drinking Water: Drinking water sources (Private and public) have been sampled extensively within the current investigation area by DuPont and Chemours since 2001. PFAS data for approximately the past five years are presented and discussed.
- Section 6.3.2 PFAS in Off-Site Surface Water: Ohio River surface water has been sampled several times between 2002 and present by several organizations including DuPont, Chemours and EPA.
- Section 6.3.3 PFAS in Off-Site Sediment: EPA analyzed small stream sediments in West Virginia and Ohio in 2022-2023.
- Section 6.3.4 PFOA in Off-Site Groundwater: Groundwater was sampled for PFOA from temporary well points at the Little Hocking Water Association well field in Ohio in 2002 and 2006.
- Section 6.3.5 PFOA in Off-Site Soil: Soil associated with the groundwater sampling in 2002 at the LHWA well field. In addition, in 2005 and 2011, soil was sampled at private residences in West Virginia and Ohio in 2005 following dry

time periods and wet time periods. Further, soil was again sampled for PFOA from some of those same locations in 2011.

- Section 6.3.6 PFOA in Off-Site Ambient Air: Ambient air was sampled and analyzed for PFOA in 2005 at the same private residences in West Virginia and Ohio where soil was sampled for the wet and dry time period events.
- Section 6.3.7 PFOA in Off-Site Rain: Rain was sampled and analyzed for PFOA in 2005 at the same private residences in West Virginia and Ohio where soil was sampled for the wet and dry time period events.
- Section 6.3.8 PFOA in Off-Site Small Mammals: Small mammals were sampled for PFOA in 2005 from the LHWA well field.
- Section 6.3.9 PFOA in Off-Site Fish: Two species of fish were sampled for PFOA from a location in the Ohio River downstream of the Site Outfalls.
- Section 6.3.10 PFOA in Off-Site Produce: Produce was sampled for PFOA from the same location where soil was sampled in West Virginia and Ohio in 2011.
- Section 6.3.11 PFOA in Off-Site Beef and Beef Fodder: Beef and beef fodder were sampled from the one location in Ohio where beef is raised and from where soil and produce were sampled in 2011.

Appendix K provides the PFAS results for off-site environmental media presented in Section 6.3.1. Sections 6.3.2 and 6.3.3 provide PFAS data for surface water and sediments that were generated by EPA. Appendix L provides the PFAS results generated by EPA.

6.3.1 PFAS in Off-Site Drinking Water

In this section, PFAS results for private water supplies and PWSs in West Virginia and Ohio that were sampled by DuPont or Chemours as part of their surveying and sampling program are presented. Following that information are PFAS results for three PWSs in the vicinity of the Site that were sampled in 2019 by the USGS working in cooperation with the West Virginia Department of Environmental Protection (WVDEP) and West Virginia Department of Health and Human Resources (WVDHHR).

Surveying and PFOA Sampling of private water supplies and PWSs in West Virginia and Ohio first began in 2001 and continued under various regulatory programs and legal orders. Surveying and sampling of private water supplies and PWSs is ongoing under the Safe Drinking Water Act FAOC, which was effective as of January 6, 2017, when EPA, DuPont, and Chemours agreed to amend the 2009 Consent Order in accordance with the terms and conditions contained in the FAOC. Additional details of the surveying and sampling programs are included in Section 4.3.1.

The most recent 2009 Consent Order as Amended Quarterly Progress Report (QPR) titled *2023 Annual and Quarterly Progress Report No. 28 – 2009 Consent Order as Amended* (AECOM, 2024b) includes validated sampling results through December 12, 2023 for PFAS obtained for new drinking-water sources sampled and from the monitoring of GAC treatment systems installed at private water systems and PWSs.

At select private and public water systems, sampling for HFPO-DA, in addition to PFOA, began in the first quarter of 2018 at the request of EPA. In addition, on a voluntary basis as of April 20, 2022, Chemours began analyzing private drinking water samples by EPA Method 537.1, which reports 18 PFAS, including PFOA and HFPO-DA. At this same

time, the RL was voluntarily changed by Chemours from 0.010 µg/L to 0.002 µg/L (from 10 to 2 ng/L), adjusting for dilution and sample volume for PFAS for the private and public water sampling programs. Further, in the third quarter of 2022, residential GAC system PT samples were also analyzed by EPA Method 537.1 for 18 PFAS by Chemours on a voluntary basis. Then, on a voluntary basis, in the third quarter of 2023, the annual private GAC system PT samples were analyzed by EPA Method 1633 DRAFT, which reports 40 PFAS to a RL of 0.002 µg/L, including PFOA and HFPO-DA.

PFAS in Private Drinking Water – DuPont and Chemours Investigation

Figures 1 and 2 in the *2023 Annual and Quarterly Progress Report (QPR) No. 28 – 2009 Consent Order as Amended* (AECOM, 2024b), reproduced here as Figures 6-3 and 6-4, show locations of private drinking water sources (wells and springs) that have or had PFOA greater than 0.07 µg/L or above the treatment criterion at the time the source was sampled. Figure 6-3 provides the locations of private drinking water sources where GAC treatment system have been installed. Figure 6-4 provides the locations of private drinking water sources, which have been connected to a PWS or have bottled water provided or are included in other situations as described in Table 7 of the that report. Figure 3 from that QPR, reproduced here as Figure 6-5, shows the locations of private drinking water sources sampled that had PFOA less than 0.07 µg/L or were below the treatment criterion at the time the source was sampled. Note that these three figures are comprehensive and show results generated from previous surveying and sampling programs, many of which are outside of the current investigation area that is indicated by the blue outline in the figures.

Table 6-1 provides the summary of the PFAS results for private water supplies. This summary table provides a list of PFAS that have been analyzed in these samples, the number of times that the specific PFAS has been analyzed, and the number of times that the specific PFAS has been detected above the RLs[30]. For each PFAS, the range in RLs is provided for PFAS not detected above the RLs. For each PFAS detected above the RLs, a count of the number of detections above the RLs is provided as well as the range in concentrations detected. Prior to April 26, 2022, only PFOA was analyzed in the residential samples. After that date, additional PFAS beyond PFOA were analyzed as was described above. Therefore, in Table 6-1, the top row provides statistics for PFOA data collected under the FAOC from 2016 through December 12, 2023 as well as the third quarter 2023 GAC system PT sampling event. The lower portion of the table provides the summary statistics for new residential samples collected and analyzed after April 26, 2022 through December 12, 2023 as well as the results for the third quarter PT sampling of GAC systems in 2022 and 2023 for which other PFAS in addition to PFOA were analyzed.

Table 6-1 shows that of the 40 PFAS analyzed for in the private drinking water data set, only 17 have results detected above the RLs. In addition, of those 17, six were detected infrequently, specifically only in seven or fewer samples. Five more frequently detected and higher concentration PFAS that may be related to historical and/or current air and/or water discharges from the Site are HFPO-DA, PFOA, PFHxA, PFHpA, and PFBA.

[30] Amongst the same sample locations collected over time, RLs may be variable due to method differences and or due to adjustments made for sample volumes and/or dilutions.

The data for detections in these samples were used to identify the PFAS for which a set of dot maps would be generated to display the presence and distribution of PFAS detected above the RL in this data set. Then, the dot maps were developed using whichever was the most recent result or set of results available from 1) the results analyzed for 40 PFAS via EPA 1633 DRAFT, or 2) the results analyzed for 18 PFAS via EPA 537.1, or 3) the result analyzed for PFOA only. PFAS dot maps developed are listed below:

- Figure 6-6: Chemours Private Drinking Water Sample Location Map
- Figure 6-7: Chemours Private Drinking Water – PFOA Dot Map
- Figure 6-8: Chemours Private Drinking Water – PFHpA Dot Map
- Figure 6-9: Chemours Private Drinking Water – PFHxA Dot Map
- Figure 6-10: Chemours Private Drinking Water – PFBA Dot Map
- Figure 6-11: Chemours Private Drinking Water – PFBS Dot Map
- Figure 6-12: Chemours Private Drinking Water – PFPA Dot Map
- Figure 6-13: Chemours Private Drinking Water – PFHxS Dot Map
- Figure 6-14: Chemours Private Drinking Water – PFOS Dot Map
- Figure 6-15: Chemours Private Drinking Water – HFPO-DA Dot Map
- Figure 6-16: Chemours Private Drinking Water – PFOSA Dot Map
- Figure 6-17: Chemours Private Drinking Water – Other PFAS Dot Map

Note that the dot map concentration ranges are unique to each PFAS shown as indicated in the figure legends.

These dot maps show that there are similar patterns in the distribution of PFOA, PFHxA, PFHpA and to a lesser extent HFPO-DA. For these PFAS, concentrations are higher closer to the Site and to the northeast and decrease with increasing distance from the Site. PFHxA and PFHpA were residuals in the APFO used until 2000, so it not unexpected that the distribution of these two PFAS would be similar to that of PFOA. HFPO-DA replaced PFOA as a site processing aid since 2013, so the similarities in the presence of PFOA and HFPO-DA is also not unexpected. However, HFPO-DA has been used for a shorter timeframe (2013 through the present compared to the time from the 1950s to 2013) and abatement technologies have been installed that have resulted in reduced concentrations of PFAS in Site air emissions overall and subsequently the areal footprint of HFPO-DA is smaller as is shown in the dot map figures. In addition, there are localized detections (or hot spots) in the PFOA, PFHxA and PFHpA dot maps that are higher than surrounding detections.

As noted in the Interstate Technology Regulatory Council PFAS Fact Sheet 2 Naming Conventions and Use, in Table 2.6 within subsection 2.5 PFAS Used and Products, there are multiple commercially available articles of commerce from industries and applications that used PFAS, which may be found in a typical private residence including

automotive materials, biocides (herbicides and pesticides), building and construction materials, cosmetics and personal care products, guns and ammunition, household and cleaning products, paper and packaging, and textiles (upholstery, carpets), leather, and apparel (2.5 PFAS Uses and Products – PFAS — Per- and Polyfluoroalkyl Substances (itrcweb.org)). Therefore, localized “hot” spots, particularly with sulfonate PFAS, which have been identified in the private drinking water PFAS dot maps are likely present due to use, management, and disposal of these types of articles of commerce, which are unrelated to PFAS use in the fluoropolymer manufacturing processes at Washington Works. Chemours knows of no such database that tracks private use of these products on a local level such that other sources of PFAS could be definitively identified within the private drinking water data set. However, the use, management, and disposal of these types of PFAS-bearing articles of commerce by private drinking water well owners is identified here as a data gap.

While informative, the dot map analysis was limited in the conclusions that could be drawn with respect to source determination. This limitation is due to the potential for sources unrelated to the Site, although the presence of sources unrelated to the site is undetermined and is a data gap. However, to further evaluate if unique PFAS fingerprints, defined as distinct, recognizable combinations of PFAS observed in connection with a specific source, could be identified in the drinking-water data set, AECOM performed a PFAS statistical forensics analysis (AECOM, 2024a) using the same data set as was used for the dot map analysis.

Environmental statistical forensics is a multidisciplinary process that makes use of powerful statistical and data analytics methods to assess multiple types of data (e.g., chemical, geospatial, historical, and hydrogeological). Pattern-recognition techniques and compositional mixture analysis can be used to identify indicator compounds and contaminant sources for specific chemical families such as PFAS. The objective environmental statistical forensics analysis aims to impartially reveal groupings (i.e., clusters) of similar observations so that relationships within the data set can be successfully explored and modeled. The use of statistical methods, such as principal component analysis (PCA) and hierarchical clustering to differentiate chemical mixtures, is not new. In the chemical sciences, this approach has been used for decades in a wide range of applications from identifying adulterated food products to discerning distinct petroleum releases (Brereton, 2009). Recently, the widespread accessibility to statistical computing through open-source platforms like R Statistical Software (2023) has grown alongside the need for more powerful tools to investigate PFAS in the environment. This has led to the demonstration of a wide range of statistical applications in PFAS investigations, ranging from the identification of novel PFAS molecules in analytical chemistry applications (McCord and Strynar, 2019) to using PCA and hierarchical clustering to link PFAS mixtures found in blood serum to specific dietary exposure sources (Hu et al., 2018).

The statistical approach applied to the data set in this analysis is consistent with robust combinations of these same methods used by several others to investigate and define PFAS sources (Yao et al., 2014; Zhang et al., 2016; Munoz et al., 2017; Guelfo and Adamson, 2018; Hu et al., 2018; McCord and Strynar, 2019; Stoiber et al., 2020; Luo et al., 2021; Zheng et al., 2021; Ruyle et al., 2021). Based on the broad adoption of these methods in published PFAS research, there is a growing consensus that these multivariate statistical methods provide one of the most valid, effective ways to differentiate and evaluate PFAS sources.

Conceptually, the outcome of the forensic statistical analysis is a multivariate profile referred to colloquially as a PFAS fingerprint. The PFAS mixture proportions for each sample are the inputs that ultimately isolate individual groups with similar PFAS compositions; however, this is only one part of the fingerprinting process. A full fingerprint is defined by the aggregated characteristics of those PFAS mixture groups, including correlations and spatial distribution within the groups, much as an actual fingerprint is a two-dimensional collection of uniquely arranged lines and multiple fingerprints represent a single identity. Additional details of the PFAS statistical forensics analysis performed here are provided in the attached report provided as Appendix M.

During the statistical analysis, unsupervised pattern recognition via PCA and hierarchical clustering provided groups of similar chemical signatures for further exploration and identification of specific source fingerprints based on the full chemical, statistical, and spatial profile. In doing so, four clusters were identified.

PFAS in Public Water Supplies – DuPont and Chemours Investigation

GAC treatment systems have been installed by Chemours at 10 PWSs and one transient non-community water system (TWS) along the Ohio River in West Virginia and Ohio, excluding the GAC system for the Site (Figure 6-18). Prior to March 2023, PWS GAC system PT samples were analyzed for PFOA, or HFPO-DA and PFOA if HFPO-DA was detected. After March 2023, PWS GAC system samples were analyzed for the 18 PFAS by EPA 537.1. However, if HFPO-DA was not detected in the first four month's results, it was removed from the analyte list. In addition, Chemours voluntarily sampled the Parkersburg Public Service District (PSD) untreated water for 18 PFAS in February 2023.

Table 6-2 provides a summary of the PFAS results for PWS GAC treatment PT samples between 2018 through 2023. This summary table provides a list of PFAS that have been analyzed in these samples, the number of times that the specific PFAS has been analyzed, and the number of times that the specific PFAS has been detected above the RLs. For each PFAS, the range in RLs is provided for PFAS not detected above the RLs. For each PFAS detected above the RLs, a count of the number of detections above the RLs is provided as well as the range in concentrations detected. Because there is only one set of PFAS results for Parkersburg, those data are not summarized in Table 6-2. Summary information for the PWSs and TWS in Table 6-2 is presented by geographic location from north to south as shown in Figure 6-18.

The summaries provided in Table 6-2 for the PWS shown in Figure 6-18 indicate that ten PFAS are detected at the eight PWS located upstream and in the immediate vicinity of the Site and including the Site, although not all ten PFAS detected are detected at each of these eight PWSs, only PFOA, PFHxA, and PFHpA are detected at each of these PWSs. HFPO-DA is detected at PWSs closer to the Site including at BELPSD, LHWA, the Site PWS (ONSITE GAC), and LPSD, but is not detected in the PWSs located further upstream or downstream of the Site. PFOS, PFBS and PFHxS are present at highest concentrations in VPSD1, 2, and 3 and BELPSD, while these PFAS are at lower concentrations or not detected above the RL at LHWA, the ONSITE GAC and LPSD. For PWS further downstream from the LPSD, the PFAS detected are generally in the less than 10 ng/L range although maximum PFOA concentrations at Tuppers Plains and Letart over time were 17 and 10 ng/L. PFBS for these same PWSs is relatively low, but is present at a maximum of 9.7 ng/L at the Village of Pomeroy PWS. In general, PWSs downstream from the Lubeck PWS have lower detections of fewer PFAS compared to PWSs near or upstream of the Site reflecting that the presence of PFOA, PFHxA, PFHpA and HFPO-DA at these PWSs is likely attributable to Site historical and current air emissions.

Figure 6-18 and Table 6-3 provides the PFAS in PWS PT samples for the November 2023 sampling events and also shows the PFAS detected above the RL in February 2023 at the Parkersburg PSD untreated water because this is the only PFAS event that has taken place by Chemours. The same observation of more PFAS and higher detection near and upstream of the Site with fewer PFAS and lower detections downstream of the Site.

PFAS in Public Water Supplies – USGS, WVDEP and WVDHHR Investigation 2019

In 2019, the West Virginia Legislature passed a resolution that required a statewide PFAS study. The purpose of the resolution was to understand the occurrence and distribution of PFAS contamination throughout the State's rivers, lakes, and groundwater aquifers. The USGS worked in cooperation with the WVDEP and WVDHHR to collect raw-water samples at 279 public-water systems across West Virginia. Public-water systems sampled for this study were identified by the WVDHHR and included all community water systems in the State and all daycares and schools that operate their own water systems. Sampling was completed between June 2019 and May 2021, and the results were made available in a report issued by the USGS[31].

Included in this study were three PWS along the Ohio River located in the vicinity of the Site, two upstream to the north and one downstream to the south. Although the PWSs sampled in this study are not identified in the publication, it appears that one is located in the vicinity of the City of Vienna (likely the same well field as the Vienna1 GAC system installed by Chemours), one in the vicinity of Parkersburg and one in the vicinity of Lubeck (likely where Chemours installed the GAC system for the Lubeck PDS). In that study, analysis was completed for 28 PFAS using a modified version of EPA 537.1. A summary of the data in this publication related to these three PWS includes the following:

[31] *Occurrence of Per- and Polyfluoroalkyl Substances and Inorganic Analytes in Groundwater and Surface Water Used as Sources for Public Water Supply in West Virginia – Scientific Investigations Report 2022-5067*. United States Geological Survey. Reston, VA 2022. https://pubs.usgs.gov/sir/2022/5067/sir20225067.pdf. Accessed February 2024.

- PFOA plus PFOS were detected at greater than 70 ng/L at these three PWS.
- Seven or more PFAS were detected at the furthest to the north PWS and the southern PWS, while the PWS closest to the north had detection of three to four PFAS.
- The PWS located furthest to the north had a total PFAS of greater than 300 ng/L to 500 ng/L, while the PWS closest to the north had a total PFAS of greater than 100 to 300 ng/L and the southern PWS had a total PFAS concentration of greater than 500 ng/L.
- HFPO-DA was not detected at the RLs in the publication at these three PWS.

If the PWS samples are indeed the ones identified in the text above, the data are similar in PFAS detected and the magnitude of those detections between the USGS results and those generated by Chemours.

6.3.2 PFAS in Off-Site Surface Water

PFAS have been monitored in off-site surface water several times since the VI and RFI investigations of PFOA at the Site in the 1990s. PFOA was monitored in the Ohio River from locations up to 26 miles upriver from the Site and up to 53 miles downstream of the Site by DuPont in 2002 and in 2011. ORSANCO monitored PFAS in the Ohio River in 2021 and 2022, including at three locations within the same stretch of river sampled by DuPont in 2002 and 2011. Ohio River water adjacent to the Site was recently sampled by Chemours for 20 PFAS between February 2022 and February 2023. In addition, surface water bodies in creeks and streams in West Virginia and Ohio were sampled for PFAS by EPA in 2022 and 2023.

PFOA in Ohio River Water – 2002 and 2011

Included in this off-site environmental media sampling was sampling of surface water in the Ohio River. PFOA was sampled from locations up to 26 miles upriver from the Site and up to 53 miles downstream of the Site in the Ohio River in 2002 and again in 2011.

Ohio River water sampling program was completed between June 25, 2002 and October 17, 2002, when the river was at normal river stage conditions and sampling could be safely conducted. River water was sampled at up to three depths [dip (surface), mid-column, and bottom] and at up to three locations along the transects (WV-side, center, and OH-side). Twelve transects in the Ohio River were completed and their locations are shown in Figure 6-19. These transects were located as far as 26 miles upstream of the Site and 53 miles downstream of the Site. Table 6-4 provides the PFOA results for these samples. The range in concentration of PFOA in Ohio River water in 2002 was from not detected [ND (< 10 ng/L)] to a maximum of 1,050 ng/L.

The Ohio River water PFOA results collected in 2002 show that PFOA concentrations were ND or not quantifiable (NQ) for all transects upstream of the Site and Outfall 005, the outfall with the highest concentration of PFOA at that time and largest volume of water discharged. In general, for samples collected near Outfall 005, the higher concentrations were measured closer to the bank while the lower concentrations were measured further out into the river from the outfall. Concentrations in the river were detectable from near Outfall 005 and up to 18 miles downstream, and these concentrations decreased with increasing distance from Outfall 005.

PFOA sampling was repeated at many of the same locations in 2011 when the river was at normal river stage conditions and sampling could be safely conducted. PFOA results

for the 2011 sampling are provided in Table 6-5. Figure 6-19 provides the location that was resampled. River water was sampled at many of the same locations that were sampled in 2002, although a few additional further downstream river water sampling points were added adjacent to selected PWS well fields where PFOA concentrations were also being monitored. Where only one location on the transect in the river was to be sampled, river water was sampled at mid-channel from two depths, surface and mid-column. Adjacent to the Site where two or three locations on the transect in the river were resampled, river water was sampled as shown in the blow-up in Figure 6-19; and at each point, surface and mid-column depths were sampled. Table 6-5 presents the PFOA results for the 2011 river water samples. Concentrations of PFOA in river water ranged from NQ (<9.2 ng/L) to a maximum of 200 ng/L.

Figure 6-19 also provides a comparison of the 2011 river water PFOA results from the 2002 sampling. Direct comparison of the results from 2002 and 2011 is complicated by the significant lowering of the analytical detection limits between 2002 and 2011. However, the following observations can be made:

- For locations with results that were ND in 2002 and are NQ in 2011 (Stations 1 through 3), the LOQ for the 2011 results (<0.0092 µg/L or <9.2 ng/L) is comparable in 2011 to the limit of detection (LOD) for 2002 (<0.01 µg/L or <10 ng/L). These results indicate that there was essentially no change in PFOA concentration upstream of the Site between 2002 and 2011.
- There are several locations adjacent to the Site that had detectable concentrations of PFOA in 2011 that were ND in 2002 (Stations 4A through 6B). With the exception of the surface samples from locations 5A and 6A, the 2011 concentrations are approximately equal to or less than the LOD of 0.01 µg/L (10 ng/L) determined for the samples analyzed in 2002.
- For all locations downstream of the Site with detectable PFOA in both 2002 and 2011 (Stations 7 through 12), the concentrations measured in 2011 are, in most cases, less than those measured in 2002 by an order of magnitude or more.

ORSANCO PFAS Sampling of the Ohio River in 2021

During 2021 and 2022, the ORSANCO conducted a study to determine the ambient PFAS concentrations in the Ohio River from near Toronto, Ohio to near Belview, Kentucky (https://www.orsanco.org/programs/pfas/). The report and data tables from this sampling (*Ambient PFAS Levels in the Ohio River*[32]) show that three of these sampling locations are approximately within the stretch of the Ohio River sampled in 2002 and 2011. These three sampling points, at river miles 159.22 near Eureka, West Virginia, 207.90 near Long Bottom, Ohio and 257.6 near Cheshire, Ohio, are also shown in Figure 6-19. Two rounds of sampling were completed at these three locations in 2021.

Samples were analyzed for 28 PFAS as shown in the downloadable table at the link above. Of these 28 PFAS, only five were detected above the RLs and not all five were detected in all samples from both events for these three locations. Figure 6-19 provides the results for PFAS detected above the RLs for the two sampling events at these three locations. The five PFAS detected above the RLs were PFOA, PFBA, HFPO-DA, PFBS, and PFPA, At the sampling location upstream of the Site, (river mile 159.2), the maximum PFAS concentration detected was 5.75 ng/L for PFBS. At the river mile

[32] *Ambient PFAS Levels in the Ohio River*. Ohio River Valley Water Sanitation Commission. June 17, 2022. https://www.orsanco.org/data/ambient-pfas-levels-in-the-ohio-river/. Accessed February 2024.

location 207.9, located downstream of the Site, the maximum concentration detected was 8.47 ng/L for PFBA. At the third location at river mile 257.6, the maximum concentration detected was 13.60 ng/L for HFPO-DA. Although HFPO-DA is discharged through the Site outfalls, HFPO-DA was not detected above the RL in the sample closest downstream of the Site. The origin of HFPO-DA at this location, which is well over 50 river miles downstream from the Site, is uncertain.

PFAS Sampling of the Ohio River – 2022 and 2023

Ohio River water at four locations adjacent to the Site was recently sampled by Chemours for 20 PFAS between February 2022 and February 2023. During these same events, additional samples were also collected at the surface, mid column and the bottom of the water column, but these samples were only analyzed for PFOA and HFPO-DA. Table 6-6 provides a summary of the PFAS results for Ohio River water sampled between February 2022 through February 2023. This summary table provides a list of PFAS that have been analyzed in these samples, the number of times that the specific PFAS has been analyzed, and the number of times that the specific PFAS has been detected above the RLs. For each PFAS, the range in RLs is provided for PFAS not detected above the RLs. For each PFAS detected above the RLs, a count of the number of detections above the RLs is provided as well as the range in concentrations detected.

Table 6-6 shows that for the Upstream Grab samples six of the 18 PFAS are detected above the RL, but that the maximum concentration detected was 7.4 ng/L. PFAS that were detected and the concentration measured are similar to those observed in the ORSANCO data set. For the Downstream Middle Grab samples, in general, the same set of PFAS are detected and within the same range in concentrations observed for the upstream grab samples with one exception. In the downstream grab samples, the maximum PFPA concentration is 40 ng/L compared to 3.7 ng/L for the upstream grab samples. PFOA and HFPO-DA concentrations in the Downstream East, Middle and West at all three column depths are essentially the same although slightly higher in the East and West compared to the Middle.

Figure 6-20 and Table 6-7 provide the PFAS detected above the RL in Ohio River water samples for the February 2023 sampling event. This data set shows that of the 20 analyzed PFAS, none were detected above the RLs in February 2023 at the Upstream and Downstream locations. However in the Downstream transect and depth samples, PFOA and HFPO-DA were detected, but were the only PFAS analyzed. For the depth samples the same observation is made of slightly higher concentrations in the East and West locations compared to the Middle for PFOA and HFPO-DA.

Summary of Ohio River Water PFAS Results

Sampling during both events was completed during normal river stage conditions when sampling could be safely conducted. Concentrations of PFAS measured by ORSANCO in 2021 and Chemours in 2023 show in general the same set of PFAS detected, and detections are relatively low and within the same order of magnitude.

PFAS in Surface Water Investigated by EPA

In August 2022, EPA sampled surface water at 29 locations in Ohio and analyzed those samples for 25 PFAS. In February 2023, a second set of surface water locations were

sampled in Ohio and those results were analyzed for 44 PFAS. In May 2023, EPA sampled 10 surface water locations in West Virginia and those samples were also analyzed for 44 PFAS. Figure 6-21 provides the surface water sampling locations in West Virginia and Ohio. Note that the locations of the EPA surface water data set extend well beyond the location of the Chemours private drinking water data set shown in Figure 6-6. Table 6-8 provides summary results for the EPA surface water samples. This summary table provides a list of PFAS that have been analyzed in these samples, the number of times that the specific PFAS has been analyzed, and the number of times that the specific PFAS has been detected above the RLs. For each PFAS, the range in RLs is provided for PFAS not detected above the RLs. For each PFAS detected above the RLs, a count of the number of detections above the RLs is provided as well as the range in concentrations detected.

Of the 25 or 44 PFAS analyzed in EPA's surface water samples, Table 6-8 shows 11 PFAS were detected above the RL. Of these 11, only two, PFOA and PFOS were detected above the RLs more than two times. PFOA was detected in 28 of the 71 samples and PFOS was detected in 7 of the 71 samples. Figure 6-21 provides the locations of the EPA surface water samples. Note that the EPA data set extends well beyond the Chemours private drinking water data set shown in Figure 6-6. Dot maps were generated for PFOA, PFOS and the other detected PFAS as listed below:

- Figure 6-22: EPA Surface Water - PFOA Dot Map
- Figure 6-23: EPA Surface Water – PFOS Dot Map
- Figure 6-24: EPA Surface Water – Other PFAS Dot Map

The PFOA dot map for surface water (Figure 6-22) shows a mix of not detected results (black dots) and detections up to 50 ug/L (blue dots) with a few higher concentrations mixed in that are comparable in concentration to the PFOA results for drinking water sources sampled by Chemours in this same area (Figure 6-7). The PFOS dot map (Figure 6-23) and the Other PFAS dot map (Figure 6-24) show that the detections measured are randomly located with higher concentration further from the Site. The exception to this is the HFPO-DA detection to the southwest of the Site because the HFPO-DA results for drinking water sources sampled by Chemours in this same area (Figure 6-15) also shows one detection above the RL.

PFAS in Surface Water used as Drinking Water Investigated by Chemours

There were 30 drinking water springs sampled under the FAOC. Twenty-one springs had PFOA concentrations less than the EPA 2016 HA of 0.07 µg/L. The remaining nine springs qualified for treatment and have had GAC treatment systems installed. For these 30 springs, Table 6-9 provides the PFAS results for the most recent sampling for these springs with sample dates provided. Figure 6-25 also provides the PFAS results in Table 6-9 with the most recent PFOA result shown as a dot map and the detections of other PFAS above the RLs posted in data boxes. In general, these results also show higher PFOA concentrations located closer to the Site and to the northeast. Other PFAS detections are less than 10 ng/L.

6.3.3 PFAS in Off-Site Sediment

In August 2022, EPA sampled sediment at eight locations in Ohio and analyzed those samples for 25 PFAS. In May 2023, EPA sampled sediment at ten locations in West Virginia and analyzed those samples for 25 PFAS. Figure 6-21 provides the sediment sampling locations in West Virginia and Ohio. Table 6-10 provides summary results for

the EPA sediment samples. Note that the location of the EPA sediment data set extends well beyond the location of the Chemours private drinking water data set shown in Figure 6-6. This summary table provides a list of PFAS that have been analyzed in these samples, the number of times that the specific PFAS has been analyzed, and the number of times that the specific PFAS has been detected above the RLs. For each PFAS, the range in RLs is provided for PFAS not detected above the RLs. For each PFAS detected above the RLs, a count of the number of detections above the RLs is provided as well as the range in concentrations detected.

Table 6-10 shows that of the 25 PFAS analyzed in EPA's sediment samples, 10 PFAS were detected above the RL. Of these 10, only two, PFOA and PFOS were detected above the RLs more than five times. PFOA was detected in 14 of the 18 samples and PFOS was detected in 12 of the 18 samples. Based on the detection above the RLs for these sediment samples, dot maps were generated for PFOA, PFOS and the other detected PFAS as listed below:

- Figure 6-26: EPA Off-Site Sediment Dot Map - PFOA
- Figure 6-27: EPA Off-Site Sediment Dot Map - PFOS
- Figure 6-28: EPA Off-Site Sediment Dot Map – Other PFAS

Although the locations sample are spread throughout a large sampling area, the PFOA dot map (Figure 6-26) for sediment for the West Virgina locations appears to show random distribution of concentrations with no trend with distance from the Site. For the Ohio locations there appears to be a hot spot with the highest PFOA detected at a significant distance from the Site to the northeast with lower concentrations located closer to the Site. The PFOS dot map (Figure 6-27) shows similar distribution of concentration as well as a hot spot at the same location as within the PFOA data set. The Other PFAS dot map (Figure 6-28) shows that several of the sampling locations closer to the Site have no other detection of other PFAS, while locations further away from the Site do have detections above the RL in the tens to hundreds of nanograms per kilogram (ng/kg). In addition, the detections of those other PFAS, including HFPO-DA, are well outside of the areal distribution of these PFAS (Figures 6-8, 6-11, 6-15, and 6-17) in drinking water locations.

The EPA sediment data set did not include sampling of sediment in the Ohio River. Further, no sampling of Ohio River sediments has been completed by Chemours; therefore, the presence and distribution of PFAS in the sediments downstream of the Site outfalls are identified as a data gap. If the presence of PFAS is determined to be relatively significant compared to PFAS from other transport pathways, then additional evaluation of other sediment-related media (such as suspended particles) may be proposed.

6.3.4 PFOA in Off-Site Groundwater

The majority of the off-site groundwater sampled by DuPont and Chemours is groundwater that is used as drinking water, either for private water sources or for public water supplies. Results for groundwater used as drinking water supplies are provided in Section 6.3.1.

However, there were two investigations conducted by DuPont at the LHWA well field (the PWS located immediately north of the Site in Ohio on the other side of the Ohio River shown in Figure 2-11 and depicted in Figure 6-1), one in August 2002 and a second in April 2006. The first well field investigation included 1) drilling, logging of soil

and sampling (groundwater and soil) soil borings/monitoring wells, 2) monitoring groundwater elevations in all production and monitoring wells, and measuring river stage, and 3) sampling of groundwater from production and monitoring wells. The second investigation in 2006 involved the drilling, logging and sampling of groundwater and soil from the installation of five additional shallow monitoring wells (TW-6S and TW-12S through -15S) and three additional deep monitoring wells (TW-13D through TW-15D) at the LHWA well field, as well as resampling of the monitoring wells sampled in 2002. Groundwater sampling locations for the temporary borings installed in 2002 and the monitoring wells sampled in 2002 and resampled in 2006 are provided in Figure 6-29. Table 6-11 provides the groundwater results from the temporary boring installed in the August 2002 investigation. Table 6-12 provides the result for the monitoring wells sampled in 2002 and resampled in 2006 and the five shallow and three deep monitoring wells installed and sampled in 2006. (The soil results from the August 2002 and April 2006 investigations are presented in the next section.)

Table 6-11 shows that the concentrations of PFOA in groundwater from temporary borings ranged from not detected (<50 ng/L) to 75,000 ng/L. Because the LHWA well field is located in Ohio immediately across the Ohio River from the Site in Ohio (Figure 6-18), and PFOA had been used at the Site and was present in air emissions for decades, concentrations in these of orders of magnitude were not unexpected. In general, this table also shows lower PFOA concentrations with increasing sample depth, but the results are variable. However, variability in the groundwater data is expected because the rate and direction of migration of precipitation (and therefore the concentration of PFOA) likely changes due to several factors including the amount of precipitation migrating downward, the different permeabilities of the various lithologies encountered (silty clay versus sand and gravel), and whether the lithology is unsaturated or is saturated.

The comparison of the concentration of PFOA in the test wells from 2002 and 2006 provided in Table 6-12 shows in general higher concentrations of PFOA in 2006 compared to earlier sampling events, although, concentrations in Test Well 4 decreased over time. Again, given the location of the well field with respect to the Site, it is not unexpected that concentrations in groundwater would increase over time as PFOA in soil continues to leach via precipitation to groundwater.

6.3.5 PFOA in Off-Site Soil

Little Hocking Water Association, Ohio, Soil Sampling

As was stated in the previous section, LHWA soil was sampled in 2002 and 2006 at the locations indicated in Figure 6-29 during the installation of temporary wells in 2002 and during the installation of monitoring wells in 2006. Soil PFOA results are provided in Tables 6-13 and 6-14, respectively.

The soil results provided in Table 6-13 show that PFOA is found on the surface soil and throughout the subsurface in unsaturated and saturated soil. Soil data collected from borings NW-1 and SW-1 show the highest concentrations of PFOA measured were in surface soils and that lower concentrations were measured in the unsaturated zone and even lower concentrations (ND) were observed within the saturated aquifer sediments.

The soil results from the April 2006 investigation (Table 6-14) indicate that, as was observed in the soils from the first investigation, the PFOA concentrations are generally highest near the surface and decrease with increasing depth. In addition, the concentration of PFOA in surface soils in 2002, at 160 J and 110 micrograms per

kilogram (µg/kg), was higher than the range in surface soil concentrations in 2006 (approximately 30 to 60 µg/kg).

Residential Soil Sampling In Ohio and West Virginia in 2005

Additional off-site soil sampling was completed as part of the multimedia sampling completed in 2005. DuPont conducted a surface soil/grass sampling program at various locations within two miles of the Site in West Virginia and Ohio to evaluate the occurrence and distribution of PFOA within the organic-rich portion of the soil/grass column (grass shoots, grass seeds and grass flowers, and litter layer identified as the 0-1" sample) and within the mineral-rich portion of the soil/grass column (root, root zone, and soil below the root zone identified as the 1 to 6-inch sample). A 0 to 6-inch sample was also collected for comparison (as indicated by no depth interval in the sample ID). Sampling was conducted following two weather conditions, "dry" and "wet." The "dry" event was conducted on September 12, 2005, and the "wet" event was conducted on October 21, 2005. Surface soil/grass sampling for the "dry" and "wet" events were conducted at the locations indicated in Figure 6-30.

Tables 6-15 and 6-16 provide the PFOA results for the off-site soil/grass sampling for the "dry" and "wet" events, respectively. At the top of these tables are summaries by sample depth of the individual sampling data that are presented in the table. Figure 6-31 provides the average PFOA soil results for samples collected during the dry and wet events for each location. In general, the concentrations of PFOA in soils from within a 1-mile radius of the Site are higher than those from within a 1- to 2-mile radius of the Site.

Soil was also sampled associated with the sampling of small mammals at the LHWA in October 2005 (Section 6.3.8, below). These samples were collected close to soil sampling Station #5. Results of that sampling are provided in Table 6-17.

Residential Soil Sampling In Ohio and West Virginia in 2011

In 2011, soil was resampled at several of the locations sampled in 2005 but was also sampled at locations within the 2- and 5-mile radius from the Site. The purpose of this sampling was to see if PFOA concentrations had changed over time for soil resampled in 2011 and to monitor PFOA in other environmental media not sampled previously such as home-grown produce (Section 6.3.10 below). These sampling locations are shown in Figures 6-32 and 6-33. A soil sample was collected at each location from which homegrown produce was also sampled concurrently with the sampling of one of the produce types.

Results for the resampling of soil are provided in Table 6-18 and are shown in Figure 6-34. Table 6-18 shows that PFOA results for the 19 soil samples collected in Ohio ranged from non-quantifiable [NQ (<1.9 µg/kg)] to 17.6 µg/kg. PFOA results for the 10 soil samples collected in West Virginia ranged from NQ (<1.5 µg/kg) to 33 µg/kg. The soil result from the background location in Maryland was ND (<0.983 µg/kg).

Table 6-19 provides PFOA results for soil samples collected from the same locations during both soil sampling events. These locations are WV-2, WV-3, OH-11 and OH-12. This table shows that in 2005, four samples were collected at each location, two samples collected following a dry period from depths of 0 to 1 inch and 1 to 6 inches and two samples collected following a wet period from the same two depths.

Summary of Off-Site Soil Results

In summary, the off-site soil results show that in general, higher PFOA concentrations are detected closer to the Site and concentrations decrease with increasing distance from the Site. In general, PFOA concentrations are higher to the northeast of the Site. Where PFOA was sampled from various depths below ground surface, concentration decreased with increasing depth.

6.3.6 PFOA in Off-Site Ambient Air

The presence of PFOA in off-site ambient air was monitored in 2005 using the same methods as were used for the on-site fence line monitoring (Section 5.3.1). Some of the off-site sampling locations sampled for ambient air PFOA concentrations were also used for the multimedia sampling in West Virginia and Ohio. These locations are provided in Figure 6-30. Note that two on-site locations were included in this sampling and that results for those locations are provided here. PFOA results for OVS tubes and high volume samplers are presented in Tables 6-20 and 6-21. The average particle size distribution measured at each sampling station is provided in Table 6-22. Figure 6-35 provides the ambient air results averaged over the nine events.

For all the events, the highest PFOA concentrations for OVS tubes and the high-volume sampler were from these on-site sampling locations (Stations #10 and 11). These results were anticipated as these locations are closest to the air emission sources. Table 6-20 shows that the majority of the sample events for the off-site locations, OVS tubes results were ND or NQ. For events where PFOA was detected and excluding the Site fence line monitoring Stations (#10 and 11), OVS tube results ranged from 0.6 ng/m^3 to 4.8 ng/m^3. The range in PFOA measured at fence line monitoring Stations #10 and #11 was non-detect to 60.2 ng/m^3. Table 6-21 shows that excluding the Site fence line monitoring Stations (#10 and 11), the range in PFOA measured for all other monitoring stations in the 2-mile radius was 0.01 ng/m^3 to 11.9 ng/m^3 for the high-volume samplers. The range in PFOA measured at fence line monitoring Stations #10 and #11 was 10.7 ng/m^3 to 75.9 ng/m^3. Figure 6-35, which presents the averaged ambient air results, shows that the highest concentrations of PFOA in ambient air are at the Site and then decrease with increasing distance from the Site but with higher concentration observed to the northeast of the Site.

Table 6-22 provides the averaged size distribution for the events at each sampling station. This table shows that PFOA monitored at all air monitoring stations was predominantly (about 90%) in the particulate phase. This result indicated that deposition of air emissions was a key transport pathway for the CSM for migration from on-site

sources to off-site environmental media because particles are more easily deposited than vapor.

6.3.7 PFOA in Off-Site Rain

Rain data were collected during the one of the ambient air sample events discussed in the section above. Rain was sampled during Event 1 on August 25 and 26, 2005. Results for PFOA in rain are provided in Table 6-23 and are summarized in Figure 6-36. Table 6-23 shows that, while the majority of the PFOA results are NQ at the LOQ shown, the range in concentration for off-site locations was 10.2 to 52.9 ng/L. The on-site location PFOA result was 1,660 ng/L. The distribution of these results shown in Figure 6-36 are not aligned with the predominant wind direction shown in Figure 5-5. On that day, the wind was out of the southeast and directed the plume toward the northwest. This wind pattern accounts for the higher rain concentration in the northwest quadrant. Results confirm the presence of PFOA in rain near the Site and suggest the importance of wet deposition as a transport mechanism for the CSM for migration to on-site and off-site environmental media near the manufacturing area.

6.3.8 PFOA in Off-Site Small Mammals

The purpose of the small mammal sampling was to collect small mammals from a location close to the Site (the LHWA well field, Figure 6-30) and test selected small mammal blood and liver for the presence of PFOA. The meadow vole (*Microtus pennsylvanicus*) was selected for the investigation because it was present at the well field and is almost exclusively herbivorous with insects comprising a very small percentage of the diet. The meadow vole was also selected as the target species because these characteristics are optimal for identifying the occurrence of PFOA in a small mammal species. The premise of the small mammal sampling effort was that small mammals could be exposed to PFOA via dermal contact, ingestion, or inhalation of PFOA in the air and water, via dermal contact with or ingestion of vegetation containing PFOA or via dermal contact by burrowing in soil containing PFOA.

The LHWA well field was selected because it is located directly downwind from the Site. The Potomac River Works Site (which was owned by DuPont at that time) in Falling Waters, West Virginia (Figure 6-37) was selected as a suitable background location because 1) it is beyond the influence of PFOA emissions from the Site; 2) it possessed significant acreage of undisturbed habitat similar to the habitat at the LHWA property; and 3) there was no recent history of cutting the grasslands.

A sufficient number of individuals of the target species were trapped from both the Site and reference areas to obtain 10 one-gram liver masses and 10 one-milliliter plasma samples from each location. Based on weight and reproductive stage, the animals were divided into the following four groups:

- Juvenile males
- Juvenile females
- Adult males
- Adult females

Compositing of samples based on the four categories listed above was deemed necessary to obtain the requisite volumes of plasma and liver for analyses and to test for variations due to sex and level of development.

Tables 6-24 through 6-27 provide the PFOA results for plasma and liver for the LHWA and background locations, respectively. The PFOA results for all of the plasma and liver samples from both LHWA and the background location were ND at the LODs shown. However, PFOA was detected in grass and soil samples collected at the same time and in the same location as the small mammals (Table 6-17), which was unexpected because the diet of the meadow vole is almost exclusively herbivorous with insects comprising a very small percentage of the diet. Concentrations of PFOA in the grass, 0 to 1-inch soil, and 1 to 3-inch soil are 51.6 µg/kg, 43.7 µg/kg, and 85.1 µg/kg, respectively.

6.3.9 PFOA in Off-Site Fish

The purpose of the fish sampling program was to collect target fish from two locations in the Ohio River, downstream of Site Outfall 005 (Figure 6-30) and approximately 26 miles upstream of the Site (Figure 6-37), to determine the presence or absence of PFOA in fish tissue. Species with different habitat preferences and foraging modes were considered in the target species selection process. Predatory fish are excellent indicators of contamination from potentially bioaccumulative compounds. Bottom fish may accumulate chemicals through direct contact or through the ingestion of benthic invertebrates, detritus, or small fish associated with the benthos. Based on this information, the following species were targeted for sampling:

- Largemouth bass (Micropterus salmoides)
- Channel catfish (Ictalurus punctatus)

In addition, three tissue types were analyzed for PFOA from each fish sample:

- Fillets
- Viscera, including the liver
- Carcass

The fish samples were subdivided in this manner so that whole body PFOA concentration could be determined later, if deemed necessary.

- The area immediately below Outfall 005 represents a portion of the river that potentially receives PFOA from the Site; thus, fish collected from this area may be exposed to PFOA in the water discharge. The upriver area was selected as a suitable reference, or background, location because 1) it is beyond the influence of PFOA emissions from the Site, and 2) it contains similar habitat as the area downstream of Outfall 005. The Ohio River in the vicinity of Outfall 005 at the Site and at the background area is approximately 1,500 feet wide and is deep enough to allow for the operation of a boat-mounted electrofishing unit. Both areas contain suitable habitat for the two target fish species

On October 4, 2005, URS ecologists initiated fish sampling activities in two areas of the Ohio River. Efforts were made to collect fish from a range of sizes because it is unknown whether PFOA is present at higher concentrations in older (and larger) fish.

Tables 6-28 through 6-31 provide the PFOA results for the catfish and bass from near Outfall 005 and from the background sampling location, respectively. At the top of these tables, the average, maximum and minimum PFOA concentrations for each subsample (filet, viscera, and carcass) are provided. In general, viscera samples have higher concentrations than do filet or carcass samples for both species. The summary data at

the top of these tables indicate that with the exception of viscera from catfish collected near the Site, ranges and averages for each media (filet or carcass) are similar at both locations and in both species. However, there is a single result of 1440 ng/g (dry-weight basis) from the Site catfish samples that causes the average and maximum result for viscera to be much greater than all other viscera average or maximum results. If this one data point is removed, the average viscera PFOA concentration is for Site catfish is 16.60 ng/g (dry-weight basis) and is well within the range of averages observed for the background viscera samples. No correlation was observed when comparing PFOA concentration measured to the species, location, age, sex, or length of the samples.

6.3.10 PFOA in Off-Site Produce

The presence of PFOA in off-site produce was monitored at off-site locations in West Virginia and Ohio in 2011 as shown in Figures 6-32 and 6-33. Soil sampling at these same locations was discussed in Section 6.3.5. At select locations, irrigation water was also sampled. In addition to the sampling locations for homegrown produce in Ohio and West Virginia, a background sampling location in Elkton, Maryland, was identified (Figure 6-37). Based on interviews with the residents, the following homegrown produce types were identified for sampling:

- Tomatoes
- Peppers
- Green beans
- Cucumbers
- Potatoes

Produce sampling began on August 2, 2012, and was completed by September 12, 2012. Specific sampling dates are provided in Table 6-32. Locations sampled were visited several times in order to collect the desired produce types as it ripened for consumption. The five produce types identified for sampling were not always available at each location depending on the resident's growing plans and factors beyond the resident's control, such as weather conditions, plant health, and biological activity.

Table 6-32 provides the PFOA results for homegrown produce collected in West Virginia, Ohio, and at the background location in Maryland. In total, 65 produce samples were collected in Ohio, 38 in West Virginia, and five in Maryland at the background location. Of the 103 total homegrown produce samples collected within the 5-mile radius of the Site, only two had detectable amounts of PFOA. The two samples were green bean samples from Ohio at locations OH-8 and OH-11 (Figure 6-32). PFOA concentrations at OH-8 and OH-11 were 0.89 J µg/kg and 0.98 µg/kg, respectively. The remaining 101 produce samples measured ND for PFOA with the LOD ranging from <0.44 µg/kg to <0.51 µg/kg. The background location produce samples also were ND for PFOA with a LOD of <0.49 µg/kg or <0.50 µg/kg.

While WV-3 had the highest concentration of PFOA detected (33 µg/kg) in soil (Table 6-18), there was no PFOA detected in any of the produce samples at this location. Conversely, at the two locations in which produce samples did have detectable amounts of PFOA, OH-8 and OH-11, the PFOA in soil measured 2.8 µg/kg and 11 µg/kg, respectively, significantly lower than the 33 µg/kg measured at WV-3. In addition, PFOA concentrations in soil at the seven locations where untreated irrigation water was also sampled ranged from 1.7 µg/kg to 12 µg/kg (Table 6.33). PFOA concentrations in

the untreated irrigation water sources used to water the seven gardens at these locations ranged from ND (<0.0034 µg/L) to 10 µg/L. However, no PFOA was detected in the homegrown produce samples from these seven locations.

6.3.11 PFOA in Beef and Beef Fodder

Sampling of locally raised beef within the survey area was proposed at two locations, one in Ohio and one in West Virginia, based on the initial farmer interviews that showed that these farmers consumed the beef they raised. The two farm locations were expected to provide a range of PFOA concentrations and exposure potential, ranging from approximately five miles upwind (south) of the Site to approximately one mile downwind (northeast) of the Site. The farmer at location OH-11 (the location downwind of the Site, Figure 6-32) gave DuPont permission to sample beef tissue and fodder (food and water sources). However, the farmer in West Virginia ultimately decided not to slaughter any cattle during the fall or winter of 2011 or spring of 2012; therefore, sampling beef tissue was not possible at the location in West Virginia.

The sample of beef tissue was obtained from OH-11 on February 17, 2012. However, the sample was frozen when collected because the farmer forgot to notify DuPont when the animal was slaughtered in December 2011, and the beef was frozen after being processed. The sample consisted of a 1,248-gram cut of beef from the shoulder with the bone in. Due to previous problems with samples being lost in shipment, the beef sample was cut in half and 709 grams were sent to the laboratory for analysis, and 539 grams were maintained frozen by the field sampler.

A sample of hay fed to the cattle at OH-11 was also collected on February 17, 2012. The hay was grown in a field on the OH-11 farm. The sample collected consisted of 69 grams, of which 32 grams were sent to the laboratory for analysis and 37 grams were frozen and maintained by the field sampler.

Analytical results for beef, hay and untreated cattle water from OH-11 are provided in Table 6-34. The PFOA concentration in the hay measured 66 µg/kg. The PFOA concentration in the four untreated cattle water sources ranged from 9.2 µg/L to 19 µg/L. Although the hay and untreated water sources for the cattle did contain PFOA, the result for the beef tissue samples measured ND (<0.43 µg/kg) for PFOA.

6.4 Off-Site PFAS Conceptual Site Model Summary and Data Gaps

This updated Off-Site CSM shows that two types of on-site sources of PFAS have and continue to migrate to off-site environmental media. These are air emissions and discharges to the Ohio River that are the starting points from which PFAS can migrate to other environmental media, although, other pathways of migration are possible. As with the On-Site CSM, PFAS in air emissions can migrate to off-site surfaces and via precipitation to stormwater then to soil and then to groundwater, or to off-site surfaces including the Ohio River and potentially river sediments. Off-site groundwater is used for drinking water, and, where identified to have PFOA greater than the EPA 2016 HA, treatment is provided by Chemours. PFAS in process water and stormwater outfalls discharge to river water and river water recharges PWS well field adjacent to the river downstream of the Site, and, where identified to have PFOA greater than the EPA 2016 HA, treatment is provided by Chemours.

From the 1950s through 2013, APFO/PFOA was used as a processing aid for the fluoropolymer manufacturing at the Site. Off-site environmental media sampled through 2013 were only analyzed for PFOA and although the presence of a suite of PFAS

associated with the use of APFO/PFOA was not analyzed for, it is now assumed to have existed based on the presence of various PFAS in on-site environmental media. After 2013, HFPO-DA was used as a replacement chemistry for PFOA and continues to be used. PFOA and the associated suite of PFAS that was present during its use are likely mixing in with the HFPO-DA and the associated suite of PFAS that are likely present currently due to using HFPO-DA as the processing aid. Historical (prior to 2013) air emissions and discharges to the Ohio River have resulted in the presence of PFOA and likely the associated suite of PFAS in off-site environmental media.

PFAS in historical and current air emissions likely have migrated from the Site to the northeast, but also in all directions. The analysis of PFOA results in environmental media sampled from within a two-mile radius of the Site in 2005 has shown the presence of PFOA in ambient air, rain, soil, groundwater, and drinking water likely a result of the dry and wet deposition of those air emissions, although. The analysis of PFOA results in environmental media sampled from within a five-mile radius of the Site in 2011 has shown the presence of PFOA in soil, groundwater, drinking water, fish (filet, viscera and carcass), and surface water used for cattle, but not in small mammal blood or liver and only in two of 103 produce samples. Results for PFOA in these environmental media from 2005 and 2011, in general, show higher concentrations of PFOA closer to the Site and to the northeast and decreasing PFOA concentrations with increasing distance from the Site.

Although not specifically identified as a data gap, resampling of soil and groundwater at the locations within the five-mile radius of the Site, which were sampled in 2011, for a longer list of PFAS, including PFOA, would allow for the continued evaluation of the presence of PFOA over time for some of those media and would allow for the determination of the presence and distribution of other PFAS in those environmental media. In addition, sampling of surface water and associated sediment at locations within the five-mile radius to determine the presence and distribution of PFAS closer to the Site than the locations sampled by EPA should be evaluated. Sampling of sediments in the Ohio River near Site outfalls has been identified as a data gap. If the presence of PFAS is determined to be relatively significant compared to PFAS from other transport pathways, then additional evaluation of other sediment-related media (such as suspended particles) may be proposed. Activities proposed to complete this multimedia sampling within five miles of the Site and to fill the data gaps listed above will be proposed in the Sampling and Analysis Work Plan to be submitted within 90 calendar days of EPA’s approval of this updated CSM as required by Section V.48 of the RCRA 3013 Order.

Drinking water sources were sampled for PFOA beginning in 2001. Beginning in April 2022 drinking water sampled was analyzed for 18 PFAS. PT samples for locations where GAC treatment system have been installed were analyzed for 40 PFAS in the third quarter of 2023. Evaluation of these results has allowed for the determination of the presence and distribution of 17 PFAS in drinking water within the current EPA approved investigation area. Of these 17 PFAS, six are detected above the RLs at lower concentrations and frequency compared to the other 11 PFAS detected. The presence and distribution of those 17 PFAS show that there are essentially five that are associated with the Site and that, as with PFOA detected in environmental media within a five-mile

radius of the Site, concentrations in drinking water are higher closer to the Site and to the northeast, and that in general, PFOA concentrations decrease with increasing distance from the Site. In addition, PFOA results for drinking water sources show that in general, the geographic edges of the current investigation area define the geographic area where PFOA concentrations are less that the EPA 2016 HA of 70 ng/L. Chemours has installed GAC treatment systems (or provided alternative treatment) where PFOA is above the EPA 2016 HA of 70 ng/L at private drinking water sources, as required by the FAOC.

In addition to PFAS in historical and current air emissions, PFAS in historical and current discharges to the Ohio River have resulted in PFAS migration to off-site environmental media downstream of the Site including Ohio River water, possibly Ohio River sediments (which is identified as a data gap in Section 6.3.3), and groundwater in PWS well fields located along the Ohio River. PFAS results for sampling of Ohio River water upstream and downstream of the Site (Section 6.3.2) shows a limited number of PFAS detected above the RLs and relatively low concentrations compared to concentrations of PFAS in process water and stormwater outfalls. PWSs upstream and downstream along the river have been sampled and Chemours has installed GAC treatment systems where PFOA is above the EPA 2016 HA of 70 ng/L, as required by the FAOC. Ohio River sediments adjacent to the Site have not yet been sampled and sediment sampling will be proposed in the Sampling and Analysis Work Plan to be submitted within 90 calendar days of EPA's approval of this updated CSM as required by the RCRA 3013 Order.

Section 6 provides the information known regarding the framework of on-site PFAS sources and the transport mechanisms and migration pathways from those sources to off-site environmental media. The current presence and distribution of PFAS other than PFOA in off-site drinking water have been established. The current presence and distribution of PFOA in off-site drinking water have also been established, as well as the geographical extent of PFOA above the EPA 2016 HA of 70 ng/L as required by the FAOC. The presence and distribution of PFOA in groundwater, produce, fish, small mammals, surface water within 2 miles of the Site were established for 2005 and for within five miles of the Site were established in 2011. However, the current presence and distribution of PFAS, including PFOA, in soil, groundwater, surface water and associated sediment within five miles of the Site should be determined. Further, the presence and distribution of PFAS in Ohio River sediment adjacent to the Site should be evaluated.

Surveying and sampling of private water supplies and PWSs is ongoing under the Safe Drinking Water Act FAOC, in accordance with the terms and conditions contained in the FAOC. As new PFAS results are finalized for this program, those data will be evaluated and used to continue to enhance and improve the Off-Site CSM.

7.0 Summary and Data Gaps of the Updated On-Site and Off-Site CSMs

The observations on the environmental setting (Section 2) and data gaps identified are summarized as follows:

- The geology, hydrogeology, and hydrology framework for the Site is summarized as follows.
  - Terraces of silt, clay, and sand overlie the Site alluvial aquifer, which consists of unconsolidated sand and gravel. Underlying this is weathered bedrock and bedrock consisting of shale and sandstone. Hydraulic conductivity in the alluvial aquifer is significantly higher than in the bedrock.
  - The direction of groundwater flow at the Site between the alluvial aquifer and the underlying bedrock is a data gap.
  - USGS data show that the river elevation can increase above normal elevations but does not decrease below 582 feet (the pool elevation of the Ohio River). As shown in the water elevation maps in Appendix C, groundwater elevations in the alluvial aquifer are, with very few exceptions, consistently lower than 582 feet.
  - Water elevations in the Site alluvial aquifer are lower than the river due to the pumping of high-volume on-site production wells. The amount of water being removed annually is higher than can be explained by infiltration of rainfall. Assuming that this volume of groundwater is not coming from the bedrock (shale and sandstone), then it is attributed to infiltration of river water recharging the alluvial aquifer. These production wells run continuously for Site use,
  - Concurrently, some of that river water is being drawn back into the alluvial aquifer due to the gradient induced by the production wells.

The observations on the Site PFAS use and management (Section 3) and data gaps identified are summarized as follows:

- APFO/PFOA was used as a polymer processing aid for Site fluoropolymer manufacturing from the 1950s through 2013 when the Site fully transitioned to using HFPO-DA as the polymer processing aid.
- One data gap identified is that the presence, handling, and use of common industrial articles of commerce which may contain PFAS, including sulfonate PFAS, at the Site are unknown and are identified here as a data gap.

- Additional abatement technologies are being installed, or are being planned for future installation, that will be designed to meet the requirements of the NPDES permit and the ACO to reduce PFAS concentrations in current air emissions and outfall discharges to the Ohio River. Ongoing PFAS sampling of the on-site sources and on-site and off-site environmental media will be used to understand the relationship between the reduction of PFAS in on-site sources and the change of PFAS concentrations in the on-site and off-site environmental media.

The observations on the Site RCRA CA, corrective measures implementation and non-RCRA corrective action (Section 4) and data gaps identified are summarized as follows:

- Under the SDWA FAOC, drinking water sources with PFOA greater than the EPA 2016 HA of 0.070 µg/L are offered treatment by Chemours. Locations where GAC treatment system are installed by Chemours are included in the Chemours ongoing OM&M program.
- No data gaps were identified related to Site RCRA CA, corrective measures implementation, and non-RCRA corrective action.

7.1 Summary of the Updated On-Site CSM and Data Gaps

The updated PFAS On-Site CSM can be summarized as follows:

- The information presented in this updated on-site CSM shows the framework for the on-site PFAS sources and the transport mechanisms and migration pathways from those sources to on-site environmental media and provides what is known regarding the presence and distribution of PFAS in on-site environmental media.
- The updated PFAS On-Site CSM indicate that PFAS historically migrated and currently migrates from the Site fluoropolymer manufacturing process via air emissions and water discharges to the Ohio River, which are primary sources of PFAS that can migrate to on-site environmental media. This does not rule out other pathways as being potential contributors.
- Secondary PFAS sources may be associated with equipment, material handling, leaks, and spills related to infrastructure.
- PFAS in Title V permitted air emissions migrates to on-site surfaces via wet and dry deposition and via precipitation to stormwater then to soil and then to groundwater, or to on-site surfaces and via precipitation to stormwater and to the river water. PFAS in NPDES permitted process water and stormwater outfalls discharge to the Ohio River and river water recharges the Site alluvial aquifer. Site groundwater and river water are used as process water for the fluoropolymer manufacturing processes at the Site.
- Historically the concentrations of PFAS emissions to on-site environmental media were higher than they are now because of several factors including the remediation of the ADPs and consolidation of those materials under the RBL/ADPs landfill cap, the installation of abatement technologies in the

manufacturing process, and the installation of a GAC treatment system for the Ranney Well to remove PFAS prior to its use as process water.

- Lower concentrations of PFAS in air emissions result in lower amounts of PFAS migrating to on-site surfaces, stormwater, soil, and groundwater.
- The PFAS data presented in this report show that PFOA and HFPO-DA are the primary PFAS detected above the RLs and are present at the highest concentration compared to other PFAS.
- In general (but variable depending on sample location and environmental media), there are also approximately five to ten other PFAS detected at concentrations an order of magnitude or two lower than PFOA and HFPO-DA as shown in the data tables presented here for Site water.
- Depending on the sample location and environmental media, there are typically another five PFAS present in on-site water at two to several orders of magnitude lower than the PFOA and HFPO-DA concentrations as shown in the data tables presented here for Site water.
- Other than the data gaps identified below, the information presented in Section 5 presents what is known about the on-site PFAS sources, the transport mechanisms, and migration pathways from those sources to on-site environmental media.

The following bullets summarize the data gaps identified while updating the On-Site CSM for the Site:

- Spent carbon from the GAC treatment system is regenerated by the supplier although the regeneration process is unknown to Chemours and the specific regeneration process is identified here as a data gap.
- HFPO-DA and other PFAS have not been analyzed in soils other than at the East Pad for the release assessment. Therefore, the presence and distribution of PFAS other than PFOA in Site soil are unknown and are identified as a data gap in the On-Site CSM.
- The presence and distribution of PFAS, other than limited results for PFOA, in the on-site fractured bedrock monitoring wells is unknown and is identified here as a data gap.
- The evaluation of PFAS concentrations over time in select monitoring wells, production wells, and process and stormwater outfalls is identified here as a data gap.
- Blennerhassett Island production wells are also used for process water at the Site. The presence and distribution of PFAS other than PFOA in process water from the Blennerhassett Island production wells have not been determined, and this is identified as a data gap in the On-Site CSM.

- Because only one sampling event was conducted for the East Well field header, additional monitoring to understand the presence and distribution of PFAS over time is identified as a data gap in the On-Site CSM.

7.2 Summary of the Updated Off-Site CSM and Data Gaps

The updated Off-Site CSM for the Site is summarized as follows:

- The updated Off-Site CSM shows that on-site sources of PFAS that have and continue to migrate to off-site environmental media. These are Title V permitted air emissions and NPDES permitted discharges to the Ohio River.
- Off-site groundwater is used for private water, and, where identified to have PFOA greater than the EPA 2016 HA, treatment is provided by Chemours. PFAS in process water and stormwater outfalls discharge to river water, and the river water recharges the PWS well field adjacent to the river downstream of the Site. Where identified to have PFOA greater than the EPA 2016 HA, treatment is provided by Chemours.
- The analysis of PFOA results in environmental media sampled from within a two-mile radius of the Site in 2005 has shown the presence of PFOA in ambient air, rain, soil, groundwater, and drinking water, likely a result of the dry and wet deposition of those air emissions.
- The analysis of PFOA results in environmental media sampled from within a five-mile radius of the Site in 2011 has shown the presence of PFOA in soil, groundwater, drinking water, fish (filet, viscera and carcass), and surface water used for cattle.
- Results for PFOA in these environmental media from 2005 and 2011, in general, show higher concentrations of PFOA closer to the Site and to the northeast and decreasing PFOA concentrations with increasing distance from the Site.
- PFOA concentrations in private drinking water are higher closer to the Site and to the northeast, and that in general, PFOA concentrations decrease with increasing distance from the Site. However, the distribution of concentrations detected in drinking water also show that at some locations, PFAS concentrations higher than adjacent locations are observed.
- In addition, PFOA results for drinking water sources show that in general, the geographic edges of the current investigation area define the geographic area where PFOA concentrations are less than the EPA 2016 HA of 70 ng/L.

- The presence of PFOA in off-site environmental media was established in 2005 and 2011.
- The information presented in Section 6 shows what is known about the on-site PFAS sources, the transport mechanisms, migration pathways from those sources to on-site environmental media.

The following bullets summarize the data gaps identified while updating the Off-Site CSM for the Site:

- Although not specifically identified as a data gap, resampling of soil and groundwater at the locations within the five-mile radius of the Site, which were sampled in 2011, for a longer list of PFAS, including PFOA, would allow for the continued evaluation of the presence of PFOA over time for some of those media and would allow for the determination of the presence and distribution of other PFAS in those environmental media.
- In addition, sampling of surface water and associated sediment at locations within the five-mile radius to determine the presence and distribution of PFAS closer to the Site than the locations sampled by EPA should be evaluated.
- Ohio River sediments adjacent to the Site have not yet been sampled and sediment sampling is identified as a data gap. If the presence of PFAS is determined to be relatively significant compared to PFAS from other transport pathways, then additional evaluation of other sediment-related media (such as suspended particles) may be proposed.
- The use, management, and disposal of PFAS-bearing articles of commerce by private drinking water well owners and evaluating this potential source is also identified as a data gap.

7.3 Path Forward

Activities to be conducted to fill the data gaps identified for the On-Site and Off-Site CSMs will be proposed in the Sampling and Analysis Work Plan to be submitted within 90 calendar days of EPA's approval of these updated On-Site and Off-Site CSMs as required by Section V.48 of the RCRA 3013 Order.

In addition, it is important to note that there are several ongoing on-site regulatory-driven PFAS monitoring programs that include sampling of monitoring wells, production wells, and process water and stormwater outfalls (i.e., the CMI and ACO). As new PFAS results are finalized for these programs, those data will be evaluated and used to continue to enhance and improve the On-Site CSM.

Further, the surveying and sampling of private water supplies and PWSs is ongoing under the SDWA FAOC, in accordance with the terms and conditions contained in the FAOC. As new PFAS results are finalized for this program, those data will be evaluated and used to continue to enhance and improve the Off-Site CSM.

Sodium dodecafluoro-3H-4,8-dioxanonanote	NaDONA	
Lithium bis[(trifluoromethyl)sulfonyl]azanide	HQ-115	

* Full names for PFAS can have multiple variations. PFAS data used in this report that is not owned by Chemours was often identified using a different compound name and required translation to the variation of the full name provided here.

** Alternate abbreviations can be found in raw data not owned by Chemours. The alternate abbreviations used were translated to those shown in the second column if data were used in tables, figures, or text.

ft = Feet
* for K16-PW01: 621.74 = top of concrete floor. 623.24 = elevation of top of concrete pump base.
** This well can only be measured if the Teflon Process Area is not in operation due to safety concerns.
- = Not measured

Table 2-2
Aquifer Hydraulic Conductivity Values
2023 Updated Conceptual Site Model Report
Chemours Washington Works Plant

Geologic Unit	Description	Range of K Values (ft/d)			Data Source
		Minumum	Maximum	Geometric Mean	
Holocene Alluvial Sediments	Interbedded and laminated silt, clay, and fine sand	0.03	2.8	--	4
Pleistocene Alluvial Sediments	Coarse-grained sand and gravel	35	871	146	1, 2, 3, 6, 7, 8, 9
Pliestocene Sediments Underlying Blennerhassett Island	Coarse-grained sand and gravel	124	374	235	1, 6
Re-worked Pleistocene Alluvial Sediments	Interbedded sand and gravel with silt	2.8	284	--	4
Dunkard Group - Bedrock[1]	Interbedded shale and sandstone with minor limestone and coal beds	0.02	5.6	0.2	5

Notes: These values are reproduced from Table 5 of the *Revised Groundwater Modeling Report*. Dated January 2003.
1. Results from Wood County only were used in the analysis. Hydraulic conductivity calculated from reported transmissivity and well depth.

ft/d = Feet per day
K = Hydraulic conductivity

40 PFAS compounds monitored are:

11Cl-PF3OUdS
1H,1H,2H,2H-perfluorodecanesulfonate (8:2 FTS)
1H,1H,2H,2H-perfluorohexanesulfonate (4:2 FTS)
2-(N-ethyl perfluoro-1-octanesulfonamido)-ethanol
2-(N-methyl perfluoro-1-octanesulfonamido)-ethanol
3:3 Fluorotelomer Carboxylic Acid
5:3 Fluorotelomer Carboxylic Acid
6:2 Fluorotelomer sulfonate
7:3 Fluorotelomer Carboxylic Acid
9Cl-PF3ONS
DONA
Hfpo Dimer Acid
N-Ethyl Perfluorooctane Sulfonamidoacetic Acid
N-ethylperfluoro-1-octanesulfonamide
N-methyl perfluoro-1-octanesulfonamide
N-Methyl Perfluorooctane Sulfonamidoacetic Acid
Perfluoro(2-ethoxyethane)sulfonic Acid
Perfluorobutane Sulfonic Acid
Perfluorobutanoic Acid
Perfluorodecane Sulfonic Acid
Perfluorodecanoic Acid
Perfluorododecane Sulfonic Acid (PFDoS)
Perfluorododecanoic Acid
Perfluoroheptane Sulfonic Acid (PFHpS)
Perfluoroheptanoic Acid
Perfluorohexane Sulfonic Acid
Perfluorohexanoic Acid
Perfluorononanesulfonic Acid
Perfluorononanoic Acid
Perfluorooctane Sulfonamide
Perfluoropentane Sulfonic Acid (PFPeS)
Perfluoropentanoic Acid
Perfluorotetradecanoic Acid
Perfluorotridecanoic Acid
Perfluoroundecanoic Acid
PFECA B
PFECA-A
PFECA-F
PFOA
PFOS

** Quarterly sampling shall be done no less frequently than quarterly
and semi-annual sampling ampling shall be done
no less frequently than semi-annually.
µg/L = Micrograms per liter

Table 3-3
Fluoropolymer Manufacturing Processes
2023 Updated Conceptual Site Model Report
Chemours Washington Works Plant

Fluoropolymer Processes	Product Type	Applications	PFOA Emission Sources	Emission Controls as of 2006
Fine Powder Process	powder	membranes for apparel, wire and cable, filled products	air emissions	Bagfilters, scrubbers and recycling recovered PFOA
			liquid and solid wastes	Mechanical filter to remove solids and carbon treatment for filtered liquid. Incineration of filter media and misc. solid processing wastes.
Polytetrafluoroethylene (PTFE) Dispersion Process	liquid	coating applications	liquid and solid wastes	Mechanical filter to remove solids and carbon treatment for filtered liquid. Incineration of filter media and misc. solid processing wastes.
Fluoroethylene Propylene (FEP) Process	cube or flake	extrudable resins used to coat wire and cable	air emissions	Bagfilters, scrubbers and recycling recovered PFOA
			liquid and solid wastes	Mechanical filter to remove solids and carbon treatment for filtered liquid. Inicineration of filter media and misc. solid processing wastes.
FEP Dispersion Process	liquid	coating applications	liquid and solid wastes	Mechanical filter to remove solids and carbon treatment for filtered liquid. Incineration of filter media and misc. solid processing wastes.
Granular Process	granular	molded products and skived sheets	air emissions	Bagfilters, scrubbers and recycling recovered PFOA
			liquid and solid wastes	Mechanical filter to remove solids and carbon treatment for filtered liquid. Incineration of filter media and misc. solid processing wastes.
PFA Process K	solid	wire, cable and semiconductor applications	air emissions	Bagfilters, scrubbers and recycling recovered PFOA
			liquid and solid wastes	Mechanical filter to remove solids and carbon treatment for filtered liquid. Incineration of filter media and misc. solid processing wastes.
PFA Dispersion Process	liquid	coating applications	liquid and solid wastes	Mechanical filter to remove solids and carbon treatment for filtered liquid. Incineration of filter media and misc. solid processing wastes.

Notes:
All data in this table were generated by the Chemours Washington Works on-site analytical laboratory.
Raw - influent water from the Ranney Well
Lead - effluent from the first carbon bed
Lag - effluent from the second carbon bed
*Polish GAC filter results are for a portion of Ranney Well GAC treated water (Lag) directed through a polishing GAC filter for use in PFA Line2 manufacturing.
ppt = parts per trillion
< - results are reported as less than the reporting limit shown

* RFI soil sampling location inadvertently not shown in Figure 5-7. These soil borings are located in the vicinity of the Burning Grounds.

mg/kg = Milligrams per kilogram
SWMU = Solid Waste Management Unit
U = The compound was analyzed for but not detected at the listed reporting limit
UI = The compound was analyzed for but not detected; the associated reporting limit has been raised due to chromatographic interference
µg/kg = Micrograms per kilogram

Relevant SWMUs:
ADPs = Anaerobic Digestion Ponds
BG = Burning Grounds
RBL = River Bank Landfill
-- = unrelated to a specific SWMU

Notes for summary data at the top of the table:

Field duplicate results were not averaged with parent sample results. Field duplicates were treated as separate samples.
Half of the limit of detection (LOD) was used to calculate the average PFOA result if result was a not detect (ND).
The limit of quantitation (LOQ) was used to calculate the average PFOA result if result was not quantifiable (NQ).
If the minimum result was ND or NQ, ND or NQ was listed, not half the LOD or the LOQ.

dup = Duplicate
g/kg = Grams per kilogram
inches bgs = Inches below ground surface
mg/kg = Milligrams per kilogram
ND = Not detected at the limit of detection shown
µg/kg = Micrograms per kilogram

Included in this table are the results finalized between 8/21/2018 and 12/12/2023.
Ranney Well granular activated carbon (GAC) treatment system installation was completed between September 2021 and November 2021. Samples collected after installation identified as “post-GAC” are treated water, summarized from 12/1/2021 to 12/12/2023. Samples collected prior to installation identified as "pre-GAC" are untreated water, summarized from 8/21/2018 to 8/30/2021.
Refer to Table 1-1 for a list of PFAS full names for the abbreviations used in this table.

ng/L = Nanograms per liter
RL = Reporting limit

Included in this table are the results finalized between 8/21/2018 and 12/12/2023.
Refer to Table 1-1 for a list of PFAS full names for the abbreviations used in this table.
Water from the Ranney Well is used for process water. The Ranney Well granular activated carbon (GAC) treatment system installation was completed between September 2021 and November 2021. Results for Outfall 002 prior to the installation of the Ranney Well GAC treatment system and identified as "pre-GAC" results are summarized from 8/21/2018 to 8/30/2021. Results for Outfall 002 subsequent to the installation of the Ranney Well GAC treatment system and identified as "post-GAC" results are summarized from 12/1/2021 to 12/12/2023.

ng/L = Nanograms per liter
RL = Reporting limit

Outfall 002 post-Ranney GAC data is for the most recent event after to the estimated time of Ranney well's GAC installation (prior to 12/12/2023).
Outfall 002 pre-Ranney GAC data is for the most recent event that analyzes for more than PFOA and HFPO-DA prior to the Ranney well's GAC installation (in September 2021).
Refer to Table 1-1 for a list of PFAS full names for the abbreviations used in this table.

< = Not detected at the reporting limit
J = Reported value may not be accurate or precise
ng/L = Nanograms per liter
UJ = Not detected. Reporting limit may not be accurate or precise

Outfall 019 data is for the most recent event that analyzes for more than PFOA and HFPO-DA prior to 12/12/2023.
Refer to Table 1-1 for a list of PFAS full names for the abbreviations used in this table.

< = Not detected at the reporting limit
J = Reported value may not be accurate or precise
ng/L = Nanograms per liter
R = Unusable result
UJ = Not detected. Reporting limit may not be accurate or precise

Included in this table are only the results finalized between 8/21/2018 and 12/12/2023.
Parkersburg Public Service District (PPSD) was not included in these summaries as there was only one sampling event for PFAS in the time frame evaluated. The data for that event can be found in Table 6-3.
Refer to Table 1-1 for a list of PFAS full names for the abbreviations used in this table.

ng/L = nanograms per liter
RL = Reporting limit

						12	WV-side	dip	WWK-R-TS	12-1S	0.113	113	7/11/2002
						12	WV-side	dip	WWK-R-TS	12-1S-2 (DUP)	0.123	123	7/11/2002

* Note PFOA data reported in this table as ND (<0.01) is reported in the EIM database as (<0.05).

DUP = Duplicate sample
ND = Not detected at the limit of detection shown
ng/L = Nanograms per liter
NQ = Detected at a level between the MDL and the reporting limit (RL); result is not quantifiable
µg/L = Micrograms per liter

ft bgs = Feet below ground surface
J = Compound present, reported value may not be accurate or precise
mg/kg = Milligrams per kilogram
ND = Not detected at the listed method detection limit (MDL)
NQ = Detected at a level between the MDL and the reporting limit (RL); result is not quantifiable
ND<MDL<NQ<RL
RL = Limit of quantitation (LOQ) adjusted for actual sample weight and % moisture. Nominal LOQ = 2 µg/kg
µg/kg = Micrograms per kilogram
UJ = Not detected, the LOQ may be inaccurate or imprecise

* Starting in July 2005, Limit of Detection (LOD) and Limit of Quantitiation (LOQ) were determined on at least a quarterly basis using the signal to noise determination described in the Phase II QAPP. ND = Not detected at or above the LOD.

ft bgs = Feet below ground surface
mg/kg = Milligrams per kilogram
ND = Not detected at the limit of detection shown
NQ = Not quantifiable. Detected at a concentration above the LOD and below the LOQ
µg/kg = Micrograms per kilogram

Notes for summary data at the top of the table:
Field duplicate results were not averaged with parent sample results. Field duplicates were treated as separate samples.
Half of the limit of detection (LOD) was used to calculate the average PFOA result if result was a not detect (ND).
The limit of quantitation (LOQ) was used to calculate the average PFOA result if result was not quantifiable (NQ).
If the minimum result was ND or NQ, ND or NQ was listed, not half the LOD or the LOQ.

inches bgs = Inches below ground surface
mg/kg = Milligrams per kilogram
NQ = Detected at a level between the MDL and the reporting limit (RL); result is not quantifiable
ug/kg = micrograms per kilogram

Field duplicate results were not averaged with parent sample results. Field duplicates were treated as separate samples.
Half of the limit of detection (LOD) was used to calculate the average PFOA result if result was a not detect (ND).
The limit of quantitation (LOQ) was used to calculate the average PFOA result if result was not quantifiable (NQ).
If the minimum result was ND or NQ, ND or NQ was listed, not half the LOD or the LOQ.

inches bgs = Inches below ground surface
NQ = Detected at a level between the MDL and the reporting limit (RL); result is not quantifiable
mg/kg = Milligrams per kilogram
µg/kg = Micrograms per kilogram

Station 4B	ND	No sample	NQ	ND	ND	ND	No Runtime Data[7]
Station 5A	NQ	0.6	NQ	ND	ND	ND	4.3
Station 5B	NQ	0.61	NQ	NQ	ND	ND	4.3
Station 6A	ND	1.5	ND	ND	ND	ND	4.8
Station 6B	ND	No sample	No Runtime Data	NQ	ND	ND	4.2
Station 7A	ND	ND	NQ	1.2	1.8	ND	ND
Station 7B	ND	ND	ND	1.3	1.8	NQ	ND
Station 8A	ND	ND	2.2	ND	ND	ND	ND
Station 8B	ND	No sample	2.1	ND	NQ	ND	ND
Station 9A	ND	NQ	NQ	ND	ND	ND	ND
Station 9B	ND	No sample	NQ	ND	ND	ND	ND
Station 10A	33.7	25.1	26.6	25.7	31.5	36.8	60.2
Station 10B	34.8	23.9	2.04	23.3	26.8	ND	58.6

1. Co-located tubes were installed at each location as samples “A” and “B”.
2. Station 3 as originally planned became unavailable for sampling and was removed from the sampling plan.
3. No OVS tube concentrations could be calculated for Events 3 or 4. Pump calibration equipment malfunctioned during Events 3 and 4 such that reliable air volume data could not be recorded for any location. These events were repeated in order to fulfill DuPont's commitment to complete a minimum of seven full events.
4. ND (not detected) means that PFOA was not detected below the analytical Limit of Detection (LOD) for a particular sample batch. LOD values ranged from 0.09 to 0.64 ng/tube fraction for Events 1 – 9. Batch specific LOD values are noted with raw data in Appendices 3.2 through 3.10 of the May 3, 2006 Quarterly MOU Status Report #2, Phase II Monitoring/Sampling Work Plan, Dupont Washington Works (OPPT-2004-0113 PFOA Site-related Environmental Assessment Program).
5. NQ (not quantifiable) means that PFOA was not detected below the analytical Limit of Quantitation (LOQ) for a particular sample batch. LOQ values ranged from 0.43 to 3.2 ng/tube fraction for Events 1 – 9. Batch specific LOQ values are noted with raw data in Appendices 3.2 through 3.10 of the May 3, 2006 Quarterly MOU Status Report #2, Phase II Monitoring/Sampling Work Plan, Dupont Washington Works (OPPT-2004-0113 PFOA Site-related Environmental Assessment Program).
6. OVS tube supplies ran short during Event 2; therefore co-located tubes were installed at only 3 of 9 locations.
7. In two cases, no concentrations could be calculated because pump timer equipment malfunctioned and runtime was not recorded.

ND = Not detected at the limit of detection shown
ng/m^3 = Nanograms per cubic meter
NQ = Not quantified at the limit of quantification shown

WWK-X-CAT-S-10	A	filet	0.983
	B	viscera	1440
	C	carcass	1.15

Notes for summary data at the top of the table:

Field duplicate results were not averaged with parent sample results. Field duplicates were treated as separate samples.

Half of the limit of detection (LOD) was used to calculate the average PFOA result if result was a not detect (ND

The limit of quantitation (LOQ) was used to calculate the average PFOA result if result was not quantifiable (NQ

If the minimum result was ND or NQ, ND or NQ was listed, not half the LOD or the LOQ.

ng/g = Nanograms per gram

NQ = Detected at a level between the MDL and the reporting limit (RL); result is not quantifiable

Notes:
1. By the end of 2013, the transition to HFPO-DA as a replacement chemistry for PFOA was complete.
2. Ranney Well underwent installation of a granular activated carbon (GAC) treatment system between September 2021 and November 2021.
3. Timeframes and concentration ranges are variable in the charts shown.

TASK NUMBER: 23002	AECOM 248 Chapman Road Suite 101 Newark, DE 19702	OUTFALL 002 AND OUTFALL 005 – PFOA AND HFPO-DA OVER TIME	PROJECT NO.: 60713438

Notes:

1. Ranney Well granular activated carbon (GAC) treatment system installation was completed between September 2021 and November 2021. Samples collected after installation identified as “post-GAC” are of treated water. Samples collected prior to installation identified as “pre-GAC” are of untreated water and data shown are the last untreated results prior to the GAC treatment installation.
2. Posted databoxes contain PFAS concentration data in units of nanograms per liter (ng/L) for PFAS detected above the reporting limit for the last sampling event occurring between the dates of 8/21/2018 and 12/12/2023, with the sample date as indicated.
3. See Table 1-1 for a list of PFAS abbreviations used.
4. J = Reported value may not be accurate or precise.

Notes:

1. Water from the Ranney Well is used for process water. The Ranney Well granular activated carbon (GAC) treatment system installation was completed between September 2021 and November 2021. Results for Outfall 002 prior to the installation of the Ranney Well GAC treatment system shown are dated 7/15/21. Results for Outfall 002 subsequent to the installation of the Ranney Well GAC treatment system shown are dated 12/7/23.
2. Posted databoxes contain PFAS concentration data in units of nanograms per liter (ng/L) for PFAS detected above the reporting limit for the last sampling event occurring between the dates of 8/21/2018 and 12/12/2023, with the sample date as indicated.
3. See Table 1-1 for a list of PFAS abbreviations used.
4. J = Reported value may not be accurate or precise.

- FISH
- BEEF CATTLE
- PRODUCE

* OTHER SITUATION - SEE TABLE 7 OF THE MOST RECENT 2009 CONSENT ORDER AS AMENDED QUARTERLY PROGRESS REPORT.

NOTES:

1. DASHED CONTACTS ARE INTERPRETED.
2. INFRASTRUCTURE IS SCHEMATIC AND NOT TO SCALE.
3. FIGURE DEPICTS PRESENCE OF PFOA AND HFPO-DA, NOT MAGNITUDE OF CONCENTRATIONS. PRESENCE OF OTHER PFAS ARE NOT DEPICTED HERE.
4. ADJACENT TO THE SITE, PFAS FROM NPDES PERMITTED DISCHARGES DOES NOT FLOW THROUGH THE RIVER WATER RECHARGE TO WELL FIELDS IN OHIO. DOWNSTREAM OF THE SITE, PFAS FROM NPDES DISCHARGES MAY FLOW THROUGH RIVER WATER RECHARGE TO WELL FIELDS IN WEST VIRGINIA OR OHIO DUE TO RIVER WATER MIXING AND FLOW DYNAMICS.

ABBREVIATIONS:

GAC = GRANULAR ACTIVATED CARBON
HFPO-DA = HEXAFLUOROPROPYLENE OXIDE DIMER ACID
NPDES = NATIONAL POLLUTANT DISCHARGE ELIMINATION SYSTEM
PFAS = PER- AND POLYFLUOROALKYL SUBSTANCES
PFOA = PERFLUOROOCTANOIC ACID
PWS = PUBLIC WATER SUPPLY
ft amsl = FEET ABOVE MEAN SEA LEVEL

Legend

- ## = Numbers shown on the upper right of each flowchart item, referenced in sections 5.0 and 6.0 of the report.
- = Manufacturing Processes
- = PFAS-Bearing or Potentially Bearing Environmental Media
- = Treated Media
- = Migration Pathway
- = Treatment/Management System
- = Historical PFAS Source

Notes

The EPA 2016 Health Advisory of 0.07 µg/L (70 ng/L) is the criteria used for Chemours Drinking Water Surveying and Sampling Program.

The term "air emissions" refers to Title V permitted air emissions and the terms "Stormwater Outfalls" and "Process Water Outfalls" refer to NPDES permitted discharges to the Ohio River.

- >RL to ≤20
- >20 to ≤50
- >50 to ≤100
- >100 to ≤250
- >250

851 Regulatory Location Identifier

Notes:

1. The most recent PFOA result for each spring is represented by the dot color shown on the map. The 21 springs for which there are no data boxes posted are locations where only PFOA was analyzed and no GAC system was installed because the criteria of 0.070 micrograms per liter (µg/L) was not exceeded, alternative water supply options were selected (i.e. bottled water or connection to public water), or the offer of treatment was not accepted or not responded to. The nine springs with databoxes posted are springs with PFOA results greater than 0.070 µg/L and where GAC treatment systems have been installed; the most recent results for PFAS detected other than PFOA are posted.
2. See Table 1-1 for a list of PFAS full names for the abbreviations used in this figure.

E. I. DU PONT DE NEMOURS & COMPANY, INC. HYDROGEOLOGIC EVALUATION FOR ADDITIONAL WATER SUPPLY FROM BLENNERHASSETT ISLAND

INTRODUCTION

There are presently 4 sources of ground-water supply for Washington Works. The River Gallery and Ranney Collector, both installed under the Ohio River in the central plant area, are each capable of producing 1000 gpm (gallons per minute). The East Well Field, consisting of 7 wells installed near the bank of the river in the eastern part of the plant, has a combined capacity of 1850 gpm. The Blennerhassett Island Well Field derives 4400 gpm from 9 wells at or close to the bank of the main channel of the river on the downstream half of the Island. The total capacity from these sources is now 8250 gpm. In 1985, the average demand was 8200 gpm, but by 1987, if no new sources of supply are developed, there will be a shortfall of 500 gpm. This will increase to 1350 gpm in 1988 and to 1700 gpm in 1989.

In March 1985, Leggette, Brashears & Graham, Inc. (LBG) was retained by du Pont to prepare an investigative plan which would lead to the development of an additional ground-water supply from Blennerhassett Island. Whereas the present ground-water withdrawals are from the downstream half of the Island, the plan was to evaluate the overall potential of the entire Island.

PREVIOUS STUDIES

In September 1964, LBG recommended a testing program for the development of a ground-water supply from Blennerhassett Island. From June to September 1965, 17 test wells, 6 inches in diameter, were installed on the downstream half

of the Island, near the shore, along both the main and back channels of the Ohio River (Plate 1). Following completion, each well was test pumped for a short period of time. Based on the results of these tests, one large diameter well was installed and a three-day pumping test was performed. Data obtained from this test indicated that a significant amount of infiltration from the Ohio River could be induced by pumping wells installed along the main channel side of the Island. In 1966, 4 production wells were installed, followed by 3 in 1973 and 2 more in 1978. The 9 production wells were installed at 500-foot intervals along the main channel, and each well was completed with 20-inch diameter screen.

Data gathered by du Pont in 1978, during a study to determine the cause for the reduced yield capacities of Wells 435, 436, 437 and 438, indicated that the cone of depression on the ground-water surface resulting from pumping the Island wells was extensive and reached across the main channel in the vicinity of the pumped wells. This suggested that the resource was fully subscribed from the downstream half of the Island.

INSTALLATIONS OF TEST WELLS (1985)

An analysis of the hydrogeologic data from the 1965 testing program suggested that the permeability of the aquifer increases in the upstream direction. Therefore, this ground-water investigation was primarily focused on the upstream half of the Island. In addition, the study was designed so that there would be minimal intrusion to the development of the historical resources of the Island.

The exploratory drilling and installation of the test wells on the upstream half of the Island was conducted between October 1985 and January 1986. Thirteen test wells were drilled at the locations shown on Plate 1. Six test wells were installed to the east of Well 13, adjacent to but about 200 feet inland from the main channel at a spacing

interval of 1000 feet. Five test wells were located on the back-channel side, also 1000 feet apart and about 200 feet from the shore. In addition, 2 test wells were drilled to the west of Well 13.

The drilling of test wells was accomplished by the cable-tool method. At Sites A, D, F, K, and O an 8-inch diameter casing was installed in the unconsolidated sediments to the top of the bedrock. During the drilling of these wells, sediment samples were obtained using a bailer and the samples were described by an LBG hydrogeologist. Geologic logs of these wells are included in Appendix I. The drilling of the remaining 8 test wells was completed without supervision by a hydrogeologist. Therefore, the logs for these wells are based on the driller's descriptions of the sediments penetrated and revised by the LBG hydrogeologist when samples were available for analysis. Logs for these wells are also found in Appendix I.

The drilling of the 13 test wells coupled with data from previous studies show that there is a continuous aquifer under all of Blennerhassett Island. The aquifer is of glacio-fluvial origin and consists of coarse-grained sand and gravel overlain by finer-grained sediments. The alluvial and outwash glacial deposits overlie a shale or sandstone bedrock encountered between 45 and 65 feet below the surface. The saturated sediments on the upstream half of the Island range in thickness between 34 and 45 feet. The drilling data did not indicate any major clay barriers between the river and the aquifer at the new test wells. However, the examination and sieve analyses of samples suggest that the sediments are coarser and better sorted in the vicinity of Wells B, I, J, K, N and O. This was also confirmed by the short pumping tests conducted at each well.

The sediment samples collected from all 13 test wells were subjected to sieve analyses for grain-size determinations by Well Strainer Corporation. Samples collected from the 5 wells which were drilled under the supervision of a

hydrogeologist were also sieved by LBG personnel. The results were used to select the screen opening size for each test well.

Well construction procedures consisted of drilling and driving 8-inch casing to bedrock, inserting a 10-foot telescoping screen, equipped with a packer at the top, and setting it opposite the deepest and most permeable zone in the aquifer. The 8-inch casing was then withdrawn enough to expose the well screen. The construction details of the 13 test wells are summarized in table 1.

After completion, each well was developed by airlift pumping and mechanical surging. This was done by using the following equipment:

1. cable-tool drilling rig;
2. air compressor;
3. 4-inch diameter water eductor pipe;
4. 1½-inch air injector line installed inside of the 4-inch pipe;
5. water discharge line valve; and
6. double packer surge-block with the blocks set 2 feet apart and attached to the 4-inch eductor pipe.

The development procedure consisted of combining airlift pumping and the surging effects provided by the double packer surge block. The assembly was raised and lowered by means of the reciprocating action of the walking beam on the drilling rig at 20 to 30 strokes per minute. This operation started with the surge blocks at the upper end of the screen and proceeded downward until the bottom of the screen was reached. The surge blocks were maintained in action opposite each 2-foot interval of screen until the water discharge from the airlift pump was relatively free of sand.

WELL YIELD AND SPECIFIC CAPACITY

Following installation and development, each test well was pumped for a short period of time. The purposes of these tests were:

1. to evaluate the yield potential of a production well at the site by measuring specific capacity (yield per unit of water-level drawdown);
2. to establish the location of the test well which would be used for the long-term pumping test.

Each well was pumped at two or more pumping rates for a minimum of one hour at each rate using a temporary submersible pump. The pumping rate was measured by an open-end 4½-inch orifice on a 6-inch diameter discharge pipe. The results of these tests are listed on table 2.

The measured specific capacities show a mixed pattern. Between Wells O and B on the main channel side of the Island, with the exception of Well A, the values were high, ranging generally from 30 to 45 gpm/ft dd. Further upstream, from Wells C to F, the values are relatively low, in the 10-15 gpm/ft dd range. Along the back channel, Wells L and M have specific capacities which are approximately 12-17 gpm/ft dd while those further upstream, Wells J and K, are about 22-23 gpm/ft dd. Well I, closest to the upstream end of the island, has the highest value which is in excess of 50 gpm/ft dd.

The elevations of the tops of the screens and the static water levels are relatively constant for the upstream part of Blennerhassett Island resulting in available water-level drawdown of 29 to 35 feet (table 3). Therefore, the specific capacity has been used to indicate the most favorable sites for future production wells. From these data, the most productive wells would be located between Test Wells O and 13 on the main channel side of the Island. Somewhat less productive would be those located between Test Wells I and K along the back channel.

AQUIFER TESTING

Based on the short-term pumping tests, Well K was selected to be pumped for a 3-day period. The purposes of this test were to evaluate the effectiveness of recharge from the Ohio River and to determine the extent of the cone of depression caused by pumping production wells so that spacings between wells can be established.

Prior to the pumping test, 5 piezometers, P-1, P-2, P-3, P-4 and P-5, were installed in the vicinity of Well K. The installation of the 5 piezometers was completed by driving 2-inch diameter well points to a minimum depth of 10 feet below the water table. The locations of the piezometers are shown on Plate 1. A recording water-level gage was installed near the bank of the Ohio River for measuring the river fluctuations during the pumping test. In addition, water-level recorders were installed on Test Wells J and L.

On January 6, 1986, water levels were measured in the 13 new test wells, the 5 piezometers, the Ohio River and all available test or observation wells located on the downstream half of the Island. Beginning on January 8 and continuing until January 11, 1986, Test Well K was pumped continuously for 3 days at a rate averaging 460 gpm. During the test, water levels were measured manually periodically in the pumping well, the 5 piezometers and Wells I and M. On January 11, 1986, before the pumping test was terminated, water levels were measured again in the 13 new test wells and all available downstream wells. The water-level measurements before and at the end of the pumping test are listed in table 4.

As shown on table 4, a small drawdown response was measured in P-3 and P-5 located at 500 feet from Well K. No drawdown was observed at 1000 feet from the pumping well in Wells J and L. Piezometers P-2 and P-4 which were installed at 100 feet from Well K showed 1.97 and 1.85 feet of

drawdown, respectively. Piezometer P-1 installed 50 feet from Well K, between that well and the Ohio River, indicated 2.88 feet of drawdown. No major changes were measured in the Ohio River level during the test. Water-level drawdown values measured in the piezometers at the end of the test were plotted against the radial distances of those piezometers from the pumping well as shown on figure 1. This graph was used to compute the aquifer coefficients by the equations:

$$T = \frac{528Q}{\Delta s} \quad \text{(Cooper and Jacob)}$$

$$S = \frac{0.3\ Tt}{r_o^2}$$

where:

- T = coefficient of transmissivity in gpd/ft (gallons per day per foot width of the aquifer);
- Q = discharge rate in gpm;
- s = drawdown in feet
- S = coefficient of aquifer storage (dimensionless);
- t = elapsed time from start of pumping until stabilization of water levels in days;
- r_o = the intersection of the straight-line drawdown-distance graph with the zero drawdown axis; and,
- s = the change in drawdown per log cycle of radial distance in feet;

The drawdown-distance relationship indicates a transmissivity of approximately 116,000 gpd/ft and a storage coefficient of 8.3×10^{-3}. These data indicate that the aquifer

is highly permeable and is hydraulically semi-confined by the bedrock below and the silty, clayey sand above. The importance of the upper finer-grained stratum will be discussed later in this report.

Also shown on figure 1 is the distance at which zero drawdown occurred which is slightly more than 800 feet from the pumped well. At a distance of about 475 feet the interference drawdown was 0.5 foot while at a distance of about 275 feet the interference drawdown was 1 foot. Because of the limited available drawdown for production wells, the interference drawdown among these wells is critical. This, too, will be discussed later in this report.

The graphs on figure 2 are time-drawdown relationships for the piezometers during the pumping test at Well K. Drawdown is plotted against time since the start of pumping. It is apparent from this illustration that the effect of river recharge occurs within approximately 4 hours after pumping begins.

Ground-water temperature measured in the upstream test wells during the 3 months of investigation (November 1985 - January 1986) ranged between 53°F and 55°F. The Ohio River water temperature measured during the January 1986 pumping test was 34°F. The water temperature in Well K during the 3-day pumping test was constant at 55°F. The temperature of the water withdrawn from a production well during long-term operation depends on the temperature of the river water, distance between the well and the river, pumping rate, porosity of the sediments, temperature of ground water, and specific heat of the material in the aquifer. The changes in temperature are also associated with changes in water viscosity, which can reduce or increase the rate of ground-water flow and water infiltration from the river. Because of the short duration of pumping from Well K, insufficient information could be obtained for determining the river/ground-water temperature relationship. However, the test at

Well K was run during the winter when water temperatures were at their minimum and, therefore, the recharge conditions can be considered worst case.

Plate 2 is a map showing the configuration of the ground water surface as measured on January 6, 1986 before the start of the pumping test. It is readily apparent that in the upstream half of the Island, the ground-water surface is essentially at the level of the Ohio River, suggesting a good hydraulic connection. Plate 3 is a similar map showing the configuration of the ground-water surface at the end of the pumping test. Shown is the cone of depression caused by pumping Well K.

WATER QUALITY

Water samples were collected from 13 test wells, 5 downstream observation wells and one production well. Two samples were taken during the pumping tests performed at each test well except for Well K where 4 samples were taken. Only one sample was taken from each of the wells in the downstream half of the Island. Sampling was conducted over a period of 10 weeks between November 1, 1985 and January 11, 1986. Each water sample was measured for pH, electric conductivity, total dissolved solids and analyzed for total carbonate hardness, metals and major anions. These are presented in table 5. No analysis was made for the sample from Well O because it did not reach the laboratory.

For purposes of discussing the analyses, the last sample taken from each well is used because we believe it more truly represents the water quality in the aquifer.

The pH measurements indicate values between 6.0 and 7.7 which are normal values for ground water. Total dissolved solids (TDS) for all water samples are below the recommended upper limit for drinking water of 500 mg/l with the exception of Well A which showed a value of 560 mg/l (milligrams

per liter). Total carbonate hardness values are in excess of 150 mg/l in all wells except B, D, F and M. Water with hardness values greater than 150 mg/l is considered to be very hard (Freeze and Cherry 1979). The data show, in general, moderate levels of calcium (39 to 100 mg/l), magnesium (5.7 to 23 mg/l), and potassium (less than 0.5 to 4.0 mg/l). Although moderate levels of sodium (3.8-14 mg/l) are found in the wells from the upstream half of the island, 3 of the wells in the downstream area have levels above 20 mg/l which some consider to be the upper limit for consumption by those with heart disease.

The iron concentration ranges from less than 0.05 mg/l to as much as 2.4 mg/l. However, for the upstream half of Blennerhassett Island, the values are 0.1-0.6 mg/l while the downstream wells are in the range 1.2-2.4 mg/l except at Well 443, a pumping well, which is less than 0.05 mg/l. Moreover, in the upstream half, the wells along the main channel are 0.1-0.6 mg/l while along the back channel, the values are 0.1-0.25 mg/l.

Relatively high manganese concentrations are found in wells downstream from and including Well A, again with the exception of the pumping Well 443. High concentrations are also found in Wells F and I, the most upstream wells. Therefore, Wells B, C, D and E on the main channel and Wells M, L, K and I are within the range considered acceptable as potable water.

The other heavy metals, chloride, sulfates and nitrates all are well within standards for potable water.

EFFECT OF DOWNSTREAM PUMPING

Water levels measured on January 6 and 11 in all available wells on the Island were used to determine the approximate extent of the cone of depression caused by pumping the production wells. Plate 2 illustrates the configuration of the ground-water surface in the downstream

half of the Island on January 6, 1986 as the result of that pumping at the combined rate of 4000 gpm from the 9 production wells. Ground-water levels in the upstream half of the Island varied between 583.3 feet and 582.6 feet msl (mean sea level) while the river level was at 582.7 feet msl. Based on these data, the extent of the cone of depression is upstream from Wells 12 and 13, as shown. Therefore, the effect of pumping extends over more than half of Blennerhassett Island. Moreover, on the back channel side opposite the center of the cone of depression, there has been a ground-water level drawdown of nearly 10 feet. This suggests that there is substantial drawdown under the back channel and probably the main channel as well. If this is so, it is probably the result of the impedance of flow through the river bottom of recharge from the Ohio River which will restrict future development of ground water from Blennerhassett Island. In any event, this information strongly supports the LBG hypothesis that the ground-water resources in the downstream half of the island are fully subscribed.

Plate 3 depicts the ground-water surface on January 11, 1986 near the end of the pumping test at Well K. There is no significant change in the downstream area from that shown on Plate 2.

FUTURE GROUND-WATER DEVELOPMENT

Under present conditions, it is inadvisable to consider developing additional large quantities of ground water from the downstream half of the Island. Therefore, the major expansion of the water-supply system should take place in the upstream area recently tested. However, in view of the immediate need for more water and the existence of the pipeline as far as Well 443, some additional ground water can be withdrawn from the area upstream of that well.

Selections of areas for future ground-water development are based on the permeabilities of the sediments tested and

the quality of the water pumped. The data suggest that to minimize mutual interference among new production wells so as to maximize well yield, the spacing between adjacent wells should be a minimum of 700 feet. In addition, to use river infiltration to best advantages, the wells should be located 100 feet from the river bank. It has been LBG's observation that the Island has reached stabilization in regard to the erosional effects of raising of the river level and no further encroachment on the bank is expected. The selection of sites recommended for development and the evaluation of these sites are as follows:

Site 1 - Between Wells M and I

The selection of this site was based on testing of individual wells and the 3-day pumping test conducted at Well K. These data indicate that a total of 6 potential well sites may be developed. The proposed production wells should be installed at the locations shown on Plate 4.

It is estimated that perhaps as much as 3000 gpm from 6 individual wells can be obtained from Site 1. The use of this site for the additional water supply development has the following advantages and disadvantages.

Advantages

1. High water yield potential.

   The specific-capacity data of the test wells in this area indicate a high water yield potential (table 2). The long-term pumping test shows a high river infiltration potential in the vicinity of Well K and no significant drawdown influence more than 700 feet from the pumping well.

2. Low level of iron and manganese (table 4).

Disadvantage

1. High cost of water distribution.

The development of Site 1 would require the installation of a long pipeline.

Site 2 - Between Test Wells O and 13

It is estimated that there is a water-supply potential of approximately 1500 gpm which may be obtained from 3 wells averaging 500 gpm each in this area without serious encroachment on the existing supply. The proposed production wells should be installed between Test Wells O and 13, at the locations shown on Plate 4. The selection of this site for additional water-supply development was based on the following.

Advantages

1. High water yield potential.

The recent pumping test conducted at Wells N and O coupled with the test at Well 13 during an earlier study, indicate that the aquifer has a high yield potential at this site. The specific capacities of the 3 test wells in this area are the highest of all the wells tested, except Well I.

2. Connection to the existing water distribution system.

If there is sufficient unused capacity in the present pipeline, it would require its extension by only about 1400 feet.

Disadvantages

1. High level of manganese.

Water samples indicated 3.9 mg/l of manganese in Well N and 9.7 mg/l in Well 13. These concentrations are the highest detected in water samples collected from Blennerhassett Island wells during the present investigation.

2. Possibly some adverse effect on the existing supply wells

LONG-TERM GROUND-WATER SUPPLY OUTLOOK

It has been the LBG experience that the gradual silting of a river bottom can strongly reduce the infiltration rate and cause reductions in the capacities of supply wells dependent on recharge from this infiltration. In the Blennerhassett Island area there are 2 occurrences which have aggravated this situation. First, the construction of the Bellville Dam has probably reduced the average velocity of the Ohio River in this area resulting in the deposition of more fine-grained sediments. In addition, the difference between the level of the ground-water surface and that of the river will tend to hold and more-densely pack the fine sediments on the river bottom.

Experience has also shown that this situation is reversible. Experiments performed by LBG on the Little Miami River near Dayton, Ohio have demonstrated that infiltration can be restored by removing the layer of silt on the river bottom. However, because silting is an ongoing process, periodic scouring will have to be done to maintain a high infiltration rate.

Therefore, it can be expected that high rates of pumping, which will be realized if the additional ground-water developments are made, will be reduced with time unless remedial measures are taken from time to time.

CONCLUSIONS

1. The hydrogeologic data from the 1985 testing program indicated that the upstream half of the Island is favorable for additional water-supply development.

2. The drilling of the 13 test wells indicates the presence of a glacio-fluvial aquifer which overlies a shale or sandstone bedrock. The saturated sediments on the upstream half of the Island range in thickness from 35 to 45 feet.

3. Specific capacity tests concluded that the most productive areas for an additional water supply are located between test wells O and 13 on the main channel and between wells I and K along the back channel.

4. The 3-day pumping test conducted at Well K indicate that the Blennerhassett Island aquifer is highly permeable and hydraulically semi-confined by the aluvial sediments overlying the glacial deposits. The test data indicate that the landward radius of influence by Well K pumping was approximately 800 feet (figure 1).

5. The water quality in most of the upstream wells is within the range considered acceptable as potable water, with the exception of Wells A, F and I which show high concentrations of manganese. High manganese concentrations were also found in all downstream observation wells.

6. The effect of pumping the 9 production wells is limited to the downstream half of the Island. Substantial drawdown measured in downstream observation wells located on both main and back channel indicates that the ground-water resource in this area is fully subscribed.

7. The hydrogeologic investigation on the upstream half of the Island suggests that at least 4500 gpm can be developed in that area and that a minimum of 700 feet spacing should be maintained between adjacent production wells. The data also indicate that to take full advantage of induced infiltration from the river, the wells should be located 100 feet from the river bank.

8. Site 1, located between the Wells M and I on the upstream half of the Island along the back channel, appears to be the most favorable location for water-supply development. It is estimated that as much as 3000 gpm can be developed from this site.

9. Site 2, located in the vicinity of Test Wells O, N and 13, is the most favorable location for immediate water supply needs of Washington Works because of its proximity to the existing pipeline. Approximately 1500 gpm may be obtained from 3 wells located at this site.

10. The gradual silting of the river bottom may further reduce the infiltraiton rate and cause reduction in the capacities of water-supply wells.

RECOMMENDATIONS

1. Site 1 should be considered for the development of major water supply needs. Six production wells should be installed between Wells M and I at 700-foot intervals along the back channel, and at 100 feet from the river bank.

2. Site 2 is the most favorable location for immediate water-supply development. Three production wells should be installed at this site along the main channel of

the Ohio River, at spacing intervals and distances from the Ohio River as recommended for Site 1.

3. The production wells should be drilled and installed by the cable-tool method. Each production well should be completed with a minimum of 10 feet of 12-inch diameter stainless-steel screen and mild steel riser pipe. The well screen should be installed opposite the deepest and most permeable zone of the aquifer.

4. Each production well should be tested for 12 hours at a pumping rate between 300 and 500 gpm. Water samples for chemical analyses should be obtained 1 hour into the test and before the end of the test.

5. A preventive maintenance program should be instituted at each well. The nature of ground water indicates the potential for iron and manganese bacteria growth in the well screen and surrounding sediments. Therefore, it is recommended that a dose of chlorine be applied twice a year at each well site. The chlorination program should be conducted at both new and existing production wells.

6. Periodic scouring of the river bottom should be conducted in the vicinity of the Island in order to maintain a high infiltration rate.

7. An evaluation of the existing production wells should be conducted annually in order to determine the remedial measures for well productivity improvement. A specific capacity test for a pumping rate of 300 gpm should be conducted annually at each well site. If a decrease in specific capacity greater than 50 percent is observed after the silt layer from the river bottom was disturbed, a

variable-rate pumping test should be performed and well efficiency determined. The well efficiency data (well loss and aquifer loss) will indicate if a redevelopment program is required.

LOCAL GEOLOGY

The Blennerhassett Island area lies outside the reach of all glacial episodes that effected this region. The Ohio River valley and underlying aquifer materials are, however, of glacio-fluvial origin. The glacial materials are outwash sands and gravels from meltwaters of Wisconsin stage glaciation.

The present day Ohio River is a consequence of alteration of surface drainage patterns due to the Wisconsin glaciation. Pre-Wisconsin surface drainage was generally in a northern direction. The Wisconsin glacier formed a barrier and blocked surface drainage along its front, producing large impoundments of water and subsequently altering surface drainage patterns.

Glacial outwash deposits in the Blennerhassett Island area were probably discharged by the Muskingum River which enters the Ohio River upgradient of the site. The Muskingum River was one of the major sources of outwash to the Ohio River valley.

The glacio-fluvial deposits overlie bedrock belonging to the Permian System. The bedrock lithology is a variable sequence of shale and sandstone. The bedrock in this area is a poor source of groundwater.

Analysis of well logs shown in Appendix F for specific well sites on Blennerhassett Island indicates that the total thickness of unconsolidated deposits lies in the range of 58 to 62 feet. The upper silty clay portion of the unconsolidated deposits generally ranges from 10 to 40 feet and is considered alluvial in nature. The lower portion of the formation is comprised of predominantly sands and gravels and is more permeable. Water supply wells on the island are developed in this lower interval. The aquifer obtains most of its recharge by infiltration from the Ohio River.

Site specific subsurface conditions at each tested site are discussed as follows.

SITE SPECIFIC GEOLOGY

Site specific geology has been determined based on data obtained as a part of this project. The data includes sieve analysis and driller's well logs for du Pont water supply wells and test well 'R'. Driller's well logs address subsurface conditions the full depth of the unconsolidated materials, or approximately 60 feet and roughly 10 feet into the bedrock. Subsurface conditions at each well location are discussed below. The driller's well logs, construction details, and sieve data are shown in Appendices F and G.

Water Supply Well No. 436

Well No. 436 is located approximately 1 mile east of the west end of the island, approximately 500 feet from well Nos. 435 to the west and 437 to the east. The well was drilled to a total depth of 67 feet below land surface and completed in October of 1986. Subsurface conditions at the well are generally as follows:

0- 2 feet	-	Soil
0-42 feet	-	Silty clay (sand and gravel lens at 30 feet)
42-58 feet	-	Sand and gravel, fine to coarse
58-61 feet	-	Clay and shale
61-67 feet	-	Medium hard shale

Well No. 436 was drilled as a 30-inch diameter borehole. The well is equipped with a 20-inch diameter, 90 slot stainless steel screen which lies between 44 and 56 feet below ground level. A 20-inch diameter steel casing extends to the land surface. The bottom of the screen is not plugged and has approximately 11 feet of 20-inch steel casing welded to it. A steel plate is welded to the bottom of this extension which lies to a depth of approximately 10 feet below the top of bedrock. A gravel pack of Best No. 430 quartz sand was placed in the annular space between the borehole and 20-inch diameter inner casing and screen.

On November 11, 1986, subsequent to development and prior to test pumping, the static water level at this well was 24.6 feet below ground level or approximately Elevation 573 feet.

On November 11, 1986, subsequent to development and prior to test pumping, the static water level at this well was 24.6 feet below ground level or approximately Elevation 573 feet.

Sieve analyses at well No. 436 were performed on 11 soil samples collected between 39 and 61 feet. According to the sieve data, the formation consisted of predominantly medium sand size particles or larger.

Water Supply Well No. 444

Well No. 444 is located generally at the midpoint of the island, approximately 500 feet from well Nos. 443 to the west and 445 to the east. The well was completed in January 1987 to a total depth of approximately 69 feet below land surface. Subsurface conditions at the well are generally as follows:

0-26 feet	-	Clay
26-38 feet	-	Clay and gravel
38-42 feet	-	Clay and gravel, sandy towards bottom
42-59 feet	-	Sand and gravel
59-69 feet	-	Silty shale

Well No. 444 was drilled as a 30-inch diameter borehole. The well is equipped with a 20-inch diameter, 75 slot stainless steel screen which lies between 46 and 58 feet below ground. A 20-inch diameter steel casing extends to the land surface. The bottom of the screen is not plugged and has approximately 10 feet of 20-inch diameter steel casing welded to it. A steel plate is welded to the bottom of this 10-foot extension. A Parry No. 4 quartz sand was used to pack the annular space between the borehole and 20-inch diameter inner casing.

The static water level on April 4, 1987 was 17.7 feet below ground level or approximately Elevation 575 feet. This was subsequent to developing the well and prior to test pumping.

Sieve analyses were performed on eight soil samples collected from 33 to 59 feet below ground. The sieve data indicates that between 45 and 59 feet, the formation consists of predominantly medium sand and sized particles or larger. From 33 to 45 feet, the particle size is somewhat finer.

Water Supply Well No. 445

Well No. 445 is located generally at the midpoint of the island, approximately 500 feet from well Nos. 444 to the west and 446 to the east. In February 1987 drilling was completed at well No. 445 to a depth of approximately 68 feet below ground level. Subsurface conditions at the well are generally as follows:

0-16 feet	-	Silty clay with sand and gravel
16-25 feet	-	Clay with trace of sand and gravel
25-34 feet	-	Sand and gravel with trace of silty clay
34-58 feet	-	Sand and gravel
58-64 feet	-	Shale
64-68 feet	-	Silty shale

Well No. 445 was drilled as a 30-inch diameter borehole. The well is equipped with 20-inch diameter steel casing to a depth of 46 feet below ground. From 46 to 58 feet below ground, the well is equipped with 20-inch diameter, 75-slot stainless steel screen. Welded to the bottom of the screen is approximately 10 feet of 20-inch diameter steel casing with a steel plate welded to the lower end. A gravel pack of Parry No. 4 quartz sand was placed in the annular space between the borehole and inner casing.

The static water level on April 10, 1987, prior to test pumping and subsequent to development, was 14.1 feet below ground or approximately Elevation 586 feet.

Sieve analyses were performed on eight soil samples collected between 36 and 59 feet. The samples consisted predominantly of medium sand sized particles or larger.

Water Supply Well No. 446

Well No. 446 is located generally at the midpoint of the island, approximately 500 feet east of well No. 445. This well is the easternmost water supply well on the island. Well No. 446 was completed in January 1988 to a total depth of 64 feet below ground. Subsurface conditions at the well are generally as follows:

0-15 feet	-	Silty clay and some gravel
15-25 feet	-	Clay and gravel
25-30 feet	-	Gravel and some clay
30-50 feet	-	Sand and gravel
50-58 feet	-	Sand and gravel
58-59 feet	-	Sand and gravel, chunks of sandstone
59-63 feet	-	Cemented sand and gravel
63-64 feet	-	Sandstone

Well No. 446 was drilled as a 30-inch diameter borehole. The well is equipped with 20-inch diameter steel casing to a depth of 46 feet below ground. A 13-foot, 115-slot stainless steel screen is located from approximately 46 to 59 feet below ground level. The middle portion of the screen, from 49 to 53 feet, is blank and not exposed to the aquifer. Welded to the bottom of the screen, is a 10-foot section of 20-inch diameter steel casing with a steel plate welded to the lower end. A gravel pack of Parry No. 10 quartz sand was installed in the annular space between the borehole and inner casing.

Immediately preceding the pump test on, October 28, 1987, the static water level in well No. 446 was 22.7 feet below ground or approximately Elevation 586 feet.

Sieve analyses at well No. 446 were performed on 14 soil samples collected from ground level to top of bedrock. Samples collected from 45 to 60 feet below ground indicate that the formation is predominantly medium sized sand particles or larger. From ground level to 45 feet, the data indicates the formation is predominantly fine sand size or smaller.

Test Well 'R'

Test well 'R' was drilled to a total depth of 62 feet. The well was completed in March 1987. This test well is located approximately 35 feet from well No. 446. Test well 'R' was drilled to determine subsurface conditions at well No. 446 prior to drilling the larger diameter water well. Subsurface conditions at this well were generally as follows:

0-20 feet	-	Silty clay
20-35 feet	-	Sand and gravel, trace of silty clay
35-62 feet	-	Sand and gravel, fine to coarse

The well is equipped with 48 feet of 8 inch diameter steel casing and a 15-foot section of 7.5-inch diameter stainless steel screen. The upper 12 feet of the screen is 100 slot and the lower 3 feet is 20 slot. The bottom of the screen is affixed with a welded steel plate. No gravel pack was placed at the well.

Prior to the pump test conducted on May 4, 1987, the static water level in test Well 'R' was 23.4 feet below ground level or approximately Elevation 587 feet.

Sieve analyses were conducted on five soil samples collected from 35 to 62 feet below land surface. Data from the samples collected between 35 and 60 feet indicates the formation is predominantly medium sand sized particles, or larger. The lower 2 feet of the formation, 60 to 62 feet below ground, consisted of a much higher percentage of fine silt and sand sized particles.

A summary of well screen specifications is given in Table 1.

Table 1

PUMPING TESTS

The intent of the pumping tests was to determine specific well and aquifer characteristics and to ascertain if proposed pumps to be installed at each well could achieve the desired design rates. The desired pumping rates as determined by du Pont were:

Well No.	Design Rate in gpm
436	350
444	500
445	500
446	500

Test pumping conducted at each well would determine if the desired design rates were feasible.

Two separate pumping tests were conducted at well Nos. 436, 444, 445, and 446. The first test was a 12-hour variable rate test and the second was a 24-hour constant rate test. At test Well 'R', a variable rate test of 8 hours duration was conducted. During the pumping tests water levels were recorded by the use of battery powered water level indicators, Steven's Type F automatic recorders, or automatic pressure transducers.

The variable rate pumping test (step-drawdown) provides data from which a determination of well loss can be made. Well loss is a component of drawdown in a production well and is due to turbulent flow of water generated through the well screen and inside the casing. During variable rate tests, a well is pumped at different discharge rates at equal time intervals.

The well loss coefficient (C) can be calculated by the following equation from Jacob (1946):

$$C = \frac{(Sn/Qn - Sn\text{-}1/Qn\text{-}1)}{(Qn\text{-}1 + Qn)}$$

where

C = well loss coefficient, in sec^2/ft^5
Sn = increment of drawdown for pumping rate number n, in feet
Sn-1 = increment of drawdown for pumping rate number n-1, in feet
Qn = increment in discharge rate for pumping rate number n, in cfs
Qn-1 = increment in discharge for pumping rate number n-1, in cfs
n = pumping rate number on step (1, 2, or 3)

The value of the well loss coefficient (C), provides an indication of proper well development. The C values reported in this text represent an average of those C values calculated at each step increment during the variable rate test. Average C values less than 2.0 sec^2/ft^5 indicate a properly developed well, while those values between 2.0 and 5.0 sec^2/ft^5 indicate less adequate development. C values greater than 5.0 sec^2/ft^5 may substantiate redevelopment or rehabilitation of the well.

The constant rate pumping test is used to determine transmissivity, storage coefficient, and specific capacity. Various methods are available for calculation of aquifer characteristics. The method used for this analysis was developed by Cooper and Jacob (1946). It is estimated that steady state conditions prevailed for the data. Transmissivity is calculated by the use of the equation:

$$T = \frac{528\ Q}{\Delta s}$$

where

T = transmissivity in gallons per day per foot (gpd/ft)
Q = discharge rate in gallons per minute (gpm)
Δs = slope of the plotted line expressed as the change in drawdown in feet between any two values on the scale whose ratio is 10

The coefficient of storage is calculated with the equation:

$$S = \frac{0.3\ Tt}{r_o^2}$$

where

S = coefficient of storage (dimensionless)
T = transmissivity in gpd/ft
t_2 = time in days since pumping began
r_o^2 = intercept of the extended straight line at zero drawdown (in feet) showing the radius of approximate drawdown

Specific capacity is calculated as follows:

$$SC = \frac{Q}{dd}$$

where

SC = specific capacity at end of 24-hour test
Q = pumping rate in gpm
dd = drawdown at end of test (in feet)

A discussion of test pumping performed at the wells is presented as follows.

Pumping Test - Well No. 436

The first pumping test conducted at well No. 436 was the variable rate test performed on November 12, 1986. Pumping started at 0826 hours and concluded at 1830 hours the same day. The variable rate test was a six step test of 120-minute duration for each rate. The rates were 200 gallons per minute (gpm), 250 gpm, 300 gpm, 350 gpm, 400 gpm, and 500 gpm.

During the variable rate test, pumping well No. 436, observation well Nos. TW 437, abandoned well No. 436, TW 'P,' and Ohio River stage were monitored. Test well TW 437 is located approximately 15 feet from existing du Pont well No. 437, abandoned well No. 436 is approximately 75 feet from new well No. 436, and TW 'P' is roughly 578 feet from new well No. 436. A hydrograph for this test is shown in Appendix A. Also shown on the hydrograph is the total cumulative flow from existing operating du Pont wells on Blennerhassett Island during the test. Flow from existing du Pont wells varied between approximately 2,250 and 4,300 gpm.

As can be seen on the hydrograph, groundwater levels stabilized during each rate except during the second step in which the water level increased. It is believed this may be due to turning off a pump at a nearby production well.

Recovery was rapid at well No. 436 after pumping stopped. During the pumping test, the river stage rose about 0.25 feet. This did not have any perceptible effect on groundwater levels.

An evaluation of the well loss coefficient (C) was made based on the step test data. The average C value was calculated as 2.05 sec^2/ft^5. This value is less than the maximum of 5.0 sec^2/ft^5 for proper well development, thus indicating an efficient well.

The second test conducted was the 24-hour constant rate test. The test was begun at 1300 hours on November 13, 1986 and terminated at 1300 hours on November 14, 1986. The well was pumped at a constant rate of 430 gpm. During the test, existing island wells were flowing at 2,300 to 4,400 gpm. Observation wells used to monitor water levels were the same as during the step test. The hydrograph for the constant rate test is shown in Appendix A. Maximum observed drawdowns at well No. 436 and the observations wells were as follows:

Well 436	=	16.9 feet
TW 'P'	=	2.3 feet
Well 436 (Aban.)	=	4.0 feet
TW 437	=	1.7 feet

Water levels in Well 436 recovered to within 0.75 feet of static levels approximately one hour after cessation of pumping. During the test, the river stage fell approximately 0.50 feet.

The aquifer transmissivity determined by distance-drawdown data was calculated to be approximately 37,000 gpd/ft. This data is shown in Appendix A. The calculated radius of influence after 1 days pumpage, where no perceptable drawdown will occur as a result of pumpage from Well 436, was determined to be approximately 800 feet. At a design rate of 350 gpm, for 1

day and 180 day continuous pumpage, the calculated radius of influence is approximately 800 feet and 10,000 feet, respectively. The specific capacity of the well was 24 gpm/ft dd.

Based on the test pumping, well No. 436 can yield the desired design rate of 350 gpm.

A summary of pumping test data is shown in Table 2.

Table 2

du Pont Blennerhassett Island Well Field
Test Pumping Data for Well No. 436
Burgess & Niple, Limited

Pumping Test	Date	Discharge Rate (gpm)	Elasped Time (minutes)	Ground-water Elevation (feet)	Drawdown (feet)
Variable Rate	11-12-86				
Static		0	0	572.7	0
Step 1		200	120	563.2	9.5
Step 2		250	240	563.7	9.0
Step 3		300	360	562.0	10.7
Step 4		350	480	560.0	12.7
Step 5		400	600	558.0	14.7
Step 6		500	720	553.7	19.0
Constant Rate	11-13-86 and 11-14-86				
Static		0	0	572.8	0
Final		430	1,440	555.9	16.9

Pumping Test - Well No. 444

The first pumping test conducted at Well 444 was the variable rate pumping test performed on April 7, 1987. Pumping started at 0915 hours on the above date and concluded at 2115 hours the same day. The variable step test was a six-step test of 200, 250, 300, 350, 400, and 600 gpm. The duration of each step was approximately 120-minute duration.

During the variable rate pumping test, well No. 444, well No. 445, TW 443, and the river stage were monitored. Well No. 445 is approximately 475 feet from well No. 444, and TW 443 is roughly 25 feet from well No. 443. The hydrographs generated at TW 443, and pumping Well 444 are shown in Appendix B. Flow from existing du Pont wells on the island was approximately 4,000 gpm.

As can be seen on the hydrographs, groundwater levels increased slightly during each rate. This was due to an increase of approximately 2 feet in the river stage. The well loss coefficient was not evaluated due to the rise of the water table as affected by the Ohio River.

As shown on the hydrograph for well No. 444 and TW 443, recovery was rapid following cessation of pumping.

The second test conducted was the 24-hour constant rate test. The test commenced at 0945 hours on April 8, 1987 and terminated at 0945 hours on April 9, 1987. The well was pumped at a constant rate of 450 gpm. During this test existing island wells were flowing at approximately 4,000 gpm. Pumping Well 444, TW 443, TW 'O', and a test well at the river were monitored during the test. TW 'O' is approximately 25 feet from well No. 445 and the river TW is approximately 25 feet from well No. 444. The hydrographs for pumping Well 444 and TW 443 are given in Appendix B. The maximum observed drawdowns at Well 444 and the observation wells were as follows:

Well 444 = 7.1 feet
TW 443 = 0.8 feet
TW 'O' = 0.3 feet
TW at River = 0.6 feet

Water levels recovered to prepumping levels in a very short time after cessation of the test. During the constant rate test the river stage rose approximately 0.3 feet during the first 5 hours and then fell approximately 1.3 feet during the next 19 hours. This rise and fall in the river impacted the observed drawdown.

Distance-drawdown analysis was performed on data obtained from the constant rate test. The calculated transmissivity value was approximately 95,000 gpd/ft. The radius of influence at the 500 gpm design rate was estimated to be 600 feet for a 24-hour pumping period. For a 180-day pumping period at 500 gpm, the radius of influence was estimated to be 8,000 feet. The specific capacity of Well 444 after 24 hours pumping was 63 gpm/ft dd.

Aquifer parameters based on the constant rate test are of questionable validity due to the rise and fall in the Ohio River stage. However, the pumping test data indicates that well No. 444 can yield the desired design rate of 500 gpm.

A summary of pumping test data is shown in Table 3.

Table 3

du Pont Blennerhassett Island Well Field
Test Pumping Data for Well No. 444
Burgess & Niple, Limited

Pumping Test	Date	Discharge Rate (gpm)	Elasped Time (minutes)	Ground-water Elevation (feet)	Drawdown (feet)
Variable Rate	4-7-87				
Static		0	0	574.8	0
Step 1		200	120	572.3	2.5
Step 2		250	240	571.8	3.0
Step 3		300	360	571.1	3.7
Step 4		350	480	571.0	3.8
Step 5		400	600	570.4	4.4
Step 6		600	720	564.4	10.4
Constant Rate	4-8-87 and 4-9-87				
Static		0	0	577.4	0
Final		450	1,440	570.3	7.1

Pumping Test - Well No. 445

The variable rate pumping test was conducted at well No. 445 beginning at 0900 hours on April 10, 1987 and continued until 2100 hours the same day. The variable rate test was a six-step test with steps of 120 minutes duration each. The rates were 200, 300, 400, 500, 600, and 789 gpm.

During the variable rate pumping test well No. 445, TW 444, TW at river, TW 'O', and the Ohio river stage were monitored. TW 444 is located approximately 25 feet from well No. 445. The remaining observation wells have been previously located in earlier text. The hydrograph generated at well No. 445 is shown in Appendix C. Flow from existing du Pont wells on the island was approximately 4,000 gpm.

As can be seen on the hydrograph for well No. 445, groundwater levels stabilized during each rate indicating proper development. Following cessation of pumping, the groundwater level recovered rapidly. The river stage monitored during the variable rate test showed a slight increase. The amount of rise had no effect on groundwater elevations.

An evaluation of the well loss coefficient was made based on step test data. The average C value was calculated to be 1.34 sec^2/ft^5. This is below the approximate maximum limit (5.0 sec^2/ft^5) thus indicating a properly developed well.

The second test conducted was the constant rate test. The test began at 0830 hours on April 11, 1987 and continued until 0830 hours on April 12, 1987. The well was pumped at a constant rate of 600 gpm. During this test existing du Pont island wells were pumping at approximately 4,000 gpm. Observation points were TW 443, TW at river, TW 'O' and the river stage. The hydrographs generated at well No. 445 and TW 443 are given in Appendix C. The maximum observed drawdowns at pumping Well 445 and the observation wells were as follows:

Well 445	=	8.1 feet
TW 443	=	1.0 feet
TW 'O'	=	2.6 feet

Within approximately 3 minutes after termination of pumping, the water level in Well 445 rose to within 1 foot of the prepumping level. After 3 hours, the water level was within 6 inches of the prepumping level.

During the test, the river stage showed a slight increase, although not enough to significantly affect groundwater levels.

The aquifer transmissivity determined by distance-drawdown data shown in Appendix C was approximately 104,000 gpd/ft. The calculated radius of influence after 1 day pumpage was 370 feet. For the design rate of 500 gpm for 1 day and 180 days continuous pumping, the calculated radius of influence is approximately 370 feet and 4,000 feet, respectively. Specific capacity of well No. 445 at the end of the test was 75 gpm/ftdd.

Based on the test pumping data, well No. 445 can yield the desired design rate of 500 gpm.

A summmary of pumping test data is shown in Table 4.

Pumping Test - Well 'R'

The variable rate pumping test conducted at Well 'R' started at 1045 hours on May 9, 1987 and terminated at 1845 hours the same day. The variable rate test consisted of four steps of 60 minutes each at rates of 305, 401, 500, and 600 gpm and a final step of 240-minutes duration at 636 gpm.

During the variable rate test groundwater levels at TW 'R', TW 445, TW 444, and Ohio River stage were monitored. The hydrograph for TW 'R' is shown in Appendix D.

As can be seen on the hydrograph, groundwater levels stabilized during each rate indicating adequate development. After termination of pumping, water level recovered to 0.1 feet of the prepumping water level in approximately 45 minutes. The river stage during the test remained constant.

The average C value of the well loss constant was evaluated based on data obtained during the step test. This value was calculated as 3.42 sec^2/ft^5. This is an acceptable value for a test well.

Table 5 shows the pumping test data for the variable rate test.

Table 5

du Pont Biennerhassett Island Well Field
Test Pumping Data for Well No. 'R'
Burgess & Niple, Limited

Pumping Test	Date	Discharge Rate (gpm)	Elasped Time (minutes)	Ground-water Elevation (feet)	Drawdown (feet)
Variable Rate	5-9-87				
Static		0	0	586.90	0
Step 1		305	60	584.50	2.40
Step 2		401	120	583.10	3.80
Step 3		500	180	581.30	5.60
Step 4		600	240	579.10	7.80

Pumping Test - Well 446

The first test conducted was the variable rate pumping test. Pumping started at 0745 hours on October 28, 1987 and ended at 1945 hours the same day. The first two steps were of 240-minutes duration, at rates of 200 and 394 gpm, respectively. The third step was of 180-minutes duration at 608 gpm. The final step was pumped for 60 minutes at 800 gpm.

During the variable rate test, TW 'N', TW 'R', and TW 'O' were used as observation wells to monitor water level changes. TW 'N' is located 510 feet southeast of PW 446 and TW 'O' is located 521 feet west of PW 446. A

hydrograph for this test is shown in Appendix E. Shown on the hydrograph is the total cumulative flow from existing du Pont wells on Blennerhassett Island. According to the data, the du Pont wells were pumping at approximately 1,500 gpm. As can be seen on the hydrograph, groundwater levels stabilized during each step indicating proper development. During the test, the river stage increased 0.25 feet. This rise did not perceptibly affect groundwater levels during the test. At termination of pumping the water levels rose to the original prepumping level within 30 minutes, and to the original level within 60 minutes.

An evaluation of the well loss coefficient was made based on step test data. The average C value was determined to be 3.64 sec^2/ft^5, which indicates somewhat less than adequate development. However, because of the inherent analysis error, redevelopment of well No. 446 is not deemed necessary.

The second test conducted was a 24-hour constant rate pumping test. The test began at 0930 hours on October 29, 1987 and continued until 0930 hours, October 30, 1987. The well was pumped at a constant rate of 620 gpm. During the test, TW 'N', TW 'R', and TW 'O' were used as observation wells for water level measurements. A hydrograph for this test is given in Appendix E. Also shown on the hydrograph is the river stage and total cumulative flow from existing du Pont wells on Blennerhassett Island. The du Pont wells were pumping at approximately 1,500 gpm. As seen from the hydrograph, the river stage remained constant throughout the test. The maximum observed drawdowns during the test at Well 446 and other observation wells are as follows:

Well 446	=	13.7 feet
TW 'N'	=	0 feet
TW 'O'	=	0.25 feet
TW 'R'	=	1.0 feet

The water level at well 446 recovered to the prepumping static level approximately 1 hour following cessation of pumping.

The aquifer transmissivity determined by distance-drawdown data, shown in Appendix E, was calculated to be approximately 42,000 gpd/ft. The radius of influence at the design rate of 500 gpm was calculated to be 47 feet for 1 day continuous pumping and 680 feet for 180 days of pumpage. The specific capacity of the well was 47 gpm/ft dd.

Based on test pumping data well No. 446 can yield the desired design rate of 500 gpm.

A summary of pumping test data is shown in Table 6.

Table 6

WATER QUALITY

Groundwater samples from the test pumped wells were collected and presented to du Pont for analysis. Samples were taken at various times during the step test at TW 'R' and during constant rate tests at Well Nos. 436, 444, 445, and 446. Bottles for analysis were furnished by du Pont. Water quality parameters to be assayed were selected by du Pont. Results of water quality analysis are shown in Appendix H.

At the request of du Pont officials, an evaluation of analyses of water samples collected at TW 'O' and TW 'Q' are also presented herein. The water samples from TW 'O' and TW 'Q' were not collected as a part of this project.

Findings and a discussion of water quality analyses are discussed below.

Well No. 436

Three water samples were collected during the constant rate test, at 1400 hours on November 13, 1986; 0102 hours on November 14, 1986; and 1200 hours on November 14, 1986, at the end of the test. Results of the analyses are summarized on page H-1 of the Appendix.

In reference to parameters of U.S. EPA Primary and Secondary Drinking Water Standards, all selected parameters were below acceptable limits except for manganese. Manganese was detected at 1.10 mg/l, 1.0 mg/l, and 0.95 mg/l in the three analyzed samples. The drinking water standard for manganese is 0.05 mg/l. All other tested parameters were within normal ranges of concentrations for a sand and gravel aquifer.

Results for all parameters did not vary appreciably from the beginning of the pumping test to the end.

Well No. 444

Three water samples were collected during the constant rate test, at 0945 hours on April 8, 1987; 1130 hours the same day; and 0915 hours on April 9, 1987 at the conclusion of the test. Results of the analyses are summarized on page H-5 of the Appendix.

In reference to Primary and Secondary Drinking Water Standards, all analyzed parameters were below acceptable limits. Likewise, all tested parameters were within normal ranges of concentration for a sand and gravel aquifer.

Results for all parameters did not vary appreciably from the beginning of the pumping test to the end.

Well No. 445

Three water samples were collected during test pumping, at 0845 hours and approximately 1100 hours on April 11, 1987; and at 0815 hours on April 12, 1987, at the conclusion of the pumping test. Results of the analyses are summarized on page H-5 of the Appendix.

In reference to Primary and Secondary Drinking Water Standards, all selected parameters were well below the recommended limits and were within normal ranges of concentrations for a sand and gravel aquifer.

There was no appreciable change in water quality during the course of the test.

Well No. 446

Three water samples were collected during the pumping test at 1000 hours on October 29, 1987; at 2200 hours on October 29, 1987; and at 0900 hours on October 30, 1987, at the termination of the test. Results of the analyses are summarized on page H-12 of the Appendix.

In reference to Primary and Secondary Drinking Water Standards, all analyzed parameters were within acceptable limits except manganese which was detected at 0.3 mg/l for all three samples. All other tested parameters were within normal ranges of concentrations for a sand and gravel aquifer.

There was no appreciable increase or decrease in concentrations of the parameters during the course of the test.

Test Well 'R'

Three water samples were collected, at 1300 hours, 1100 hours, and 1800 hours, on May 4, 1987. Results of the analyses are shown on pages H-16, H-17, and H-18 of the Appendix.

In reference to Primary and Secondary Drinking Water Standards, all analyzed parameters were below the recommended limits, except for manganese which was detected at 0.50, 0.75, and 0.60 mg/l for the three samples. All other tested parameters were within normal ranges of concentrations for a sand and gravel aquifer.

Results for all parameters did not vary appreciably from the beginning of the pumping test to the end.

Test Well 'O'

Two water samples were collected on May 16, 1986. The first sample was taken at 0915 hours and the final sample was taken at 1015 hours. Results of the analyses are shown on pages H-19 and H-20 of the Appendix.

In reference to Primary and Secondary Drinking Water Standards, all analyzed parameters were below the recommended limits. Likewise, all other tested parameters were within normal ranges of concentrations for a sand and gravel aquifer.

The groundwater showed no significant change in analyzed parameters based on the two samples.

Test Well 'Q'

Three water samples were collected, at 1500 hours May 13, 1986, at 1315 hours, and 2000 hours on May 14, 1986. Results of the analyses are shown on pages H-21, H-22, and H-23 of the Appendix.

In reference to Primary and Secondary Drinking Water Standards, all analyzed parameters were below the recommended limits, and within normal ranges of concentrations for a sand and gravel aquifer.

The overall groundwater quality indicated no significant change in the analyzed parameters based on the three samples.

VIDEO SURVEY

A closed circuit video camera survey was conducted at well Nos. 436, 444, 445, and 446. The video survey was witnessed by representatives of du Pont and Burgess & Niple, Limited. The purpose of the survey was to inspect the interior of the casings and the screens.

The first video survey was conducted at well No. 436 on January 7, 1987. The top of the screen was noted as 43.6 feet below the top of the casing. The upper 2.5 to 3 feet of the screen was heavily coated with iron bacteria. Iron bacteria forms in a well by enzymatically catalyzing the oxidation of iron, precipitating hydrated ferric hydroxide. The lower portion of the screen was not coated with the iron bacteria. The well was subsequently treated for the iron bacteria and the blockage was removed.

Well No. 444 was video surveyed on April 21, 1987. The static water level was observed to be 15 feet. The quality of the video was not perfectly clear, however, the casing and screen appeared to be in good condition.

Well No. 445 was initially video surveyed on April 21, 1987. The static water level was observed to be 16 feet. The picture quality was not clear, but the inspection indicated that the screen and casing were in reasonable condition. On May 8, 1987 well No. 445 was resurveyed and the casing and screen were again observed to be in good condition.

Well No. 446 was video surveyed on November 4, 1987. Static water elevation was noted at 23 feet below the top of the casing. Large particle matter and turbidity was observed throughout the well. The picture quality was poor but the survey indicated that the screen and casing were in acceptable condition.

PERMANENT WELL PUMPS

Permanent well pumps have been installed in well Nos. 436, 444, 445, and 446. Data pertaining to each pump is shown in Appendix I. Data shown in the Appendix was supplied by the pump installation contractor. The information includes installation drawings for all wells, pump installation reports for well Nos. 436 and 446, and pump and motor detail drawings for well Nos. 444 and 445.

Byron Jackson pumps and motors were installed in each well. All motors have the same operating conditions as shown below:

125 horsepower
1,760 revolutions per minute
2,300 volts
3 phase
60 cycle

The pump bowl assembly installed in well No. 436 was a 10-inch GM eight-stage unit. The pump has a capacity of 350 gpm at 396 feet total dynamic head. Approximately 31 feet of 8-inch pump column was installed.

The pump bowl assemblies installed in well Nos. 444, 445, and 446 were 10-inch MQ-H, eight-stage units. The pumps have a capacity of 500 gpm at 396 feet total dynamic head. Approximate lengths of 8-inch column pipe installed at each well are shown below:

Well	Column Pipe Length in Feet
444	35
445	34
446	28

SUMMARY

The du Pont water supply wells on Blennerhassett Island are developed in sands and gravels underlying the Ohio River. Bedrock beneath the unconsolidated materials is shale and sandstone belonging to the Permian system. The total thickness of the unconsolidated formation at well Nos. 436, 444, 445, and 446 varied between 58 and 62 feet. The upper portion of the formation is comprised of generally silts and clays while the lower portion is permeable sands and gravels from which an adequate supply of groundwater can be obtained.

The four water supply wells developed as a part of this project were drilled as 30-inch diameter boreholes with 20-inch diameter steel casing and stainless steel screen. Quartz gravel was placed in the annular space between the borehole and 20-inch casing.

Pumping tests were conducted at the newly drilled wells to determine specific well and aquifer characteristics. Calculated well transmissivities varied between 37,000 gpd/ft and 104,000 gpd/ft, as calculated by distance-drawdown method.

The specific capacity of the four tested water supply wells as measured at the end of the constant rate test varied between 25 gpm/ft dd and 75 gpm/ft dd.

At termination of pumping following the tests, the groundwater recovery was rapid indicating adequate aquifer recharge and well development.

Based on test pumping conducted at well Nos. 436, 444, 445, and 446, the wells can yield the design capacity desired by du Pont. The desired flow rates are shown below:

Well No.	Rate in gpm
436	350
444	500
445	500
446	500

Water quality analysis at the tested sites indicated only manganese of the assayed parameters exceeded U.S. EPA Secondary Drinking Water Standards. Manganese is a regulated parameter for aesthetic reasons and not health reasons.

Closed circuit video camera surveys were conducted following test pumping at well Nos. 436, 444, 445, and 446. The survey at well No. 436 indicated that the screen was heavily coated with iron bacteria. The well was treated for the iron bacteria and the blockage was removed. The video survey of the remaining three wells indicated the screen and well interiors at all sites were acceptable.

OPEN-FILE REPORT 8903

ABSTRACT

Eight Post-Illinoian (?) fluvial surfaces occur in the upper Ohio River Valley of northwestern West Virginia. Three of the surfaces (S0, S1, and S2) are on the Ohio River floodplain, and the other five (S3, S4, S5, S6, and S7) are terraces that were within 40 m (130 ft) above low water level (a.l.w.) before river level was raised by a series of man-made dams. Height of the surfaces a.l.w. decreases downstream with increasing distance from outwash sources in Ohio and Pennsylvania. Terrace surfaces S5, S4, and S3 rise upstream from the mouth of the Muskingum River probably because of Muskingum River outwash. The upper floodplain, S2, initially decreases in relative height before leveling to a constant elevation a.l.w., whereas floodplains S1 and S0 maintain the same elevation a.l.w. throughout the study area. Soils are more intensely weathered with increasing height of the surfaces a.l.w. and increasing age.

The thick, fining-upward deposits underlying each surface consist of a combination of five facies that commonly overlap and interbed. Coarse-grained Ohio River alluvium is the coarsest and most dominant facies; it is composed of well-rounded to rounded gravels, mostly sandstone clasts, with about 5% Canadian Shield erratics, and sand. Much of the sediment in this facies was introduced into the Ohio River as outwash from the Laurentide Ice Sheet. Finer-grained tributary alluvium forms local lenses of predominantly flat, subrounded, sandstone gravel, and some

shale gravel. More sand and silt is present than in coarse-grained Ohio River alluvium. Colluvium, composed of angular sandstone clasts with more shale clasts and silt and clay than any other facies, interfingers with alluvium at the valley walls. Fine-grained Ohio River alluvium, composed of overbank silt, sand, and clay, caps the coarse deposits. Discontinous mantles of sand and silt probably represent an eolian facies.

Five radiocarbon dates were used to date S7, S4, and S2. Surfaces without radiocarbon control were dated by the relative means of tracing surfaces upstream to early-and late-Wisconsinan tills, by degree of soil development, and by morphostratigraphy. The data indicate floodplains S0, S1, and S2 are Holocene in age, terraces S3 and S4 are late Wisconsinan, and terraces S5 and S6 are early Wisconsinan. Terraces S7, at the same elevation as a segment of S5, is believed to be older than S5 (possibly Sangamonian) because it is more weathered and underlain by a higher, and therefore earlier, bedrock floor. Two relatively young radiocarbon dates show that surfaces downstream from the mouth of the Muskingum River may not correlate with those upstream on the Ohio River.

The complex set of terraces and floodplains formed during glacial advances and retreats of the pre-Wisconsinan, early- and late-Wisconsinan, successive phases of alluvial fills, and incision into the alluvium. The valley is now filled with a set of nested terraces.

ACKNOWLEDGEMENTS

I'd like to acknowledge everyone who made this thesis possible. First, thank you Dr. Robert B. Erwin and Dewey Kirstein for permission and support in expanding a West Virginia Geological and Economic Survey project into a thesis. Next, thank you Steve Kite for all of your knowledge, guidance, support, and nudging along the way. Also, thank you Bob Behling for your pertinent questions and constructive criticism.

I could not have completed this thesis without the special expertise and assistance of many people. Thank you Hobe King for all of your assistance with field work. I also appreciated field assistance, suggestions, and interest in my research from Frank Fonner, Rob Jacobson, and Mike Jordan. Thanks are also extended to Claude Mara for showing me the soils in Wetzel, Tyler, and Pleasants Counties, to Jeff Graybill for helping me with the archeology files and connecting me with people drilling on the floodplains, to Jim Smith for taking the time to show me Blennerhassett Island deposits, and to E.I. Du Pont De Nemours, Inc. for funding the wood radiocarbon date.

Analysis of the samples was smoothed by the groundwork laid by others. I extend many thanks to Allison Bell for setting up laboratory guidelines and grain-size analysis procedures. Lab assistance from Jeff Davis and Kathy Schleiff were greatly appreciated. Thanks to Tom Rymer's

excellent computer programs, analysis of the data was much easier.

Many thanks to the West Virginia Geological Survey staff for technical support in publishing this thesis. I want to especially thank Janice Bloniarz for all of her patience, diligence, and good cheer while she typed the last stages of this thesis. Also, thank you Betty Schleger and Nora Simcoe for typing the initial drafts. Illustrations by Dan Barker and Ray Strawser are always beautiful!

Last, but not least, I wish to thank all my friends and fellow graduate students, past and present, who provided me with companionship and moral support during the all too many years of this thesis.

CHAPTER 1

INTRODUCTION

STATEMENT OF PROBLEM

The lower terraces and floodplains of the upper Ohio River Valley are an important asset to West Virginia. These surfaces, occur at several levels within 40 m (130 ft) above low water level (a.l.w.) before river level was raised by a series of man-made dams. The Wisconsinan terraces and Holocene floodplains (Carlston, 1962) are wide, relatively unweathered surfaces that occur along the length of the Ohio River. In contrast, terraces greater than 40 m (130 ft) a.l.w. are narrow, weathered, scattered remnants. These upper terraces, attributed to pre-Wisconsinan glaciations (Jacobson and others, 1988), are not economically important in West Virginia and therefore are beyond the focus of this report.

The lower terraces and floodplains are important to past and present human occupation in West Virginia. Their wide, flat geometry, and location next to the Ohio River (a major water supply and transportation route) provided excellent building sites for Native American inhabitants as well as for present-day communities and industries. Underlying the surfaces are thick outwash deposits of excellent quality sand and gravel for the construction industry. This

unconsolidated sand and gravel is also an important source of groundwater for human consumption and industrial use.

Literature on the geologic history, character of the deposits, and environment of deposition for the Wisconsinan and Holocene surfaces is as limited in the upper Ohio River Valley as it is in most of West Virginia. Identifying the stratigraphy, lithology, location, and extent of the floodplains and terraces would be an important contribution to the state. A study of the outwash deposits beyond the mid-continental ice margins would broaden the information known about late Pleistocene geology in West Virginia. Knowledge of the influence of geologic history on the deposits would assist in their use as a resource for the construction industry. Also, a geologic time frame for formation of the surfaces would help archeologists in their study of early human occupation in the Ohio River Valley. Therefore, the purpose of this investigation is two-fold: (1) to more completely document the character of the lower terraces and floodplains of the upper Ohio River along the northwestern border of West Virginia, and (2) to reconstruct the late Pleistocene geologic history of the lower terraces and floodplains of the upper Ohio River Valley in West Virginia.

OBJECTIVES

The objectives of this research were to achieve the following:

1) To categorize the lower (below 40 m or 130 ft a.l.w.) Ohio River terrace and floodplain deposits by their sediment and soil attributes.
2) To determine lithology of the gravels of the terraces.
3) To develop a model of the stratigraphy of the lower alluvial terraces and floodplains of the upper Ohio River Valley along the northwestern border of West Virginia.
4) To correlate the lower fluvial surfaces along the upper Ohio River Valley in parts of Pennsylvania, West Virginia, and Ohio.
5) To use the stratigraphic model to reconstruct the geologic history of the lower alluvial terraces and floodplains of the upper Ohio River Valley.

STUDY AREA

The study area was extended into parts of Ohio and Pennsylvania to aid in correlating surfaces in West Virginia. The 266 km (165 mile) study area includes two reaches of the Ohio River and limited reaches of three glaciated tributaries (Beaver River, Little Beaver Creek, and Muskingum River). The two reaches of the Ohio River include the following: (1)

from the mouth of Beaver River, Pennsylvania (river km 40, mile 25) downstream to the south end of Wetzel County, West Virginia, at Paden City (river km 213, mile 132), and (2) from the northern end of Wood County, West Virginia (river km 266, mile 165) to Washington Bottom (river km 316, mile 196), see figure 1. The reaches of the three glaciated tributaries in the study area include: (1) the 10 km (6 miles) of Beaver River upriver from its mouth, (2) the 18 km (11 miles) of Little Beaver Creek upriver from its mouth to the Titusville and Kent Tills in the Grand River sublobe, and (3) the 16 km (10 miles) of Muskingum River upriver from its mouth. The field area is limited to the reconnoitered and sampled reaches of the Ohio River Valley in West Virginia and adjacent parts of Ohio. The field area includes the Ohio River Valley along West Virginia's northern panhandle (Hancock, Brooke, Ohio, and Marshall Counties) and Wetzel County, from Chester (river km 64, mile 40) to New Martinsville (river km 208, mile 129).

The entire length of the study area is in the Unglaciated Appalachian Plateau. The Ohio River and its tributaries are entrenched in lower Permian and Pennsylvanian age sedimentary rock units throughout the study area. These units consist of cyclothems of interbedded sandstones, siltstones, clays, shales, marine and freshwater limestones, marly shales, and coals. Crystalline rock found on the

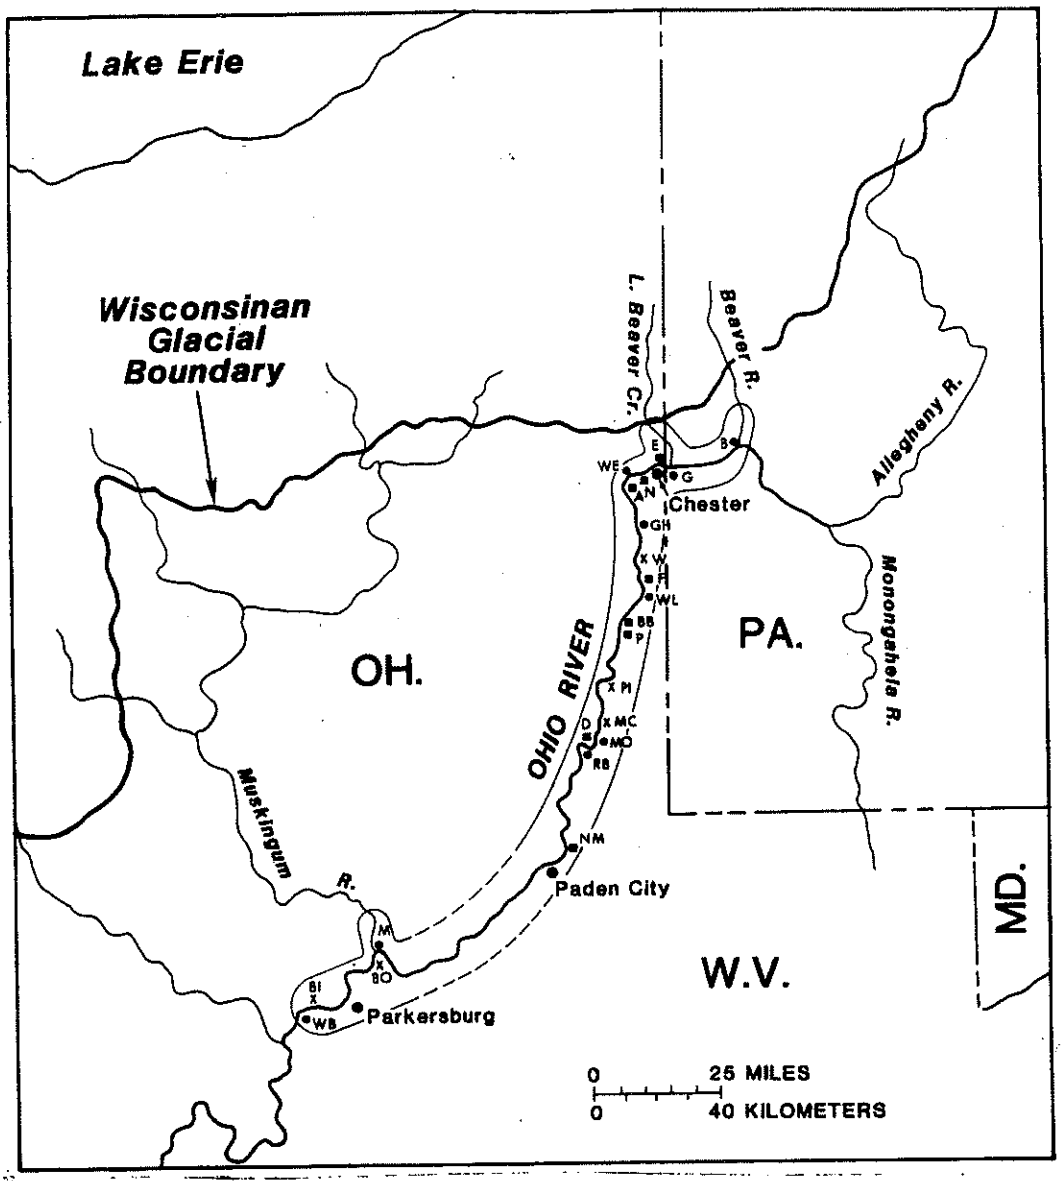

Figure 1. Location map. This map shows the study area (dashed line denotes portions not studied in the field), the Wisconsinan glacial boundary, and sites mentioned in the text. Sample sites (solid blocks) include the following: E = East End, N = Newell 1 and 2, A = Arroyo, F = Follansbee, BB = Beech Bottom, P = Power, D = Dilles Bottom, and NM = New Martinsville. Sites of radiocarbon dates (x) include: W = Weirton, PI = Pike Island, MC = McMechen, BO = Boaz, and BI = Blennerhassett Island. Other localities mentioned (solid circle) include: B = Beaver, G = Georgetown, WE = Wellsville, GH = Globe Hill, WL = Wellsburg, MO = Moundsville, RB = Round Bottom, M = Marietta, and WB = Washington Bottom.

Canadian Shield crop out about 403 km (250 miles) north of the study area (Douglas, 1968).

Topography in the study area consists of gently rolling uplands with mature drainage over much of the terrain. Along West Virginia's northern panhandle, the relief from the river to surrounding uplands is up to 274 m (900 ft). In Wood County, the relief is about 92 m (300 ft).

Floodplains and terraces are best developed inside meander bends but are discontinuous along the Ohio River's length. Maximum width of the upper Ohio River Valley is 1.1 km (0.7 mile) at Chester, gradually increasing to 1.9 km (1.2 miles) at Parkersburg. The present gradient of the river is 2 m per km or 0.5 ft per mile.

CHAPTER 2

PREVIOUS WORKS

GLACIAL HISTORY

Much of classical North American terminology for Pleistocene glacial deposits in the mid-continent may no longer be valid but is included here to aid the reader with interpreting referenced works. The Ohio and Pennsylvania tills have not been shown to be equivalent to type localities in the mid-continent, therefore, the validity of extending these time-stratigraphic units to the Ohio River Valley is questionable. Radiocarbon dates on glacial and interglacial stages used in the text are from recent correlations of continental glaciers from Indiana to New York and New Jersey (Fullerton, 1986).

Glacial history north of the study area is important to the formation of the Ohio River terraces. Pre-Wisconsinan glaciers changed the northward flowing streams in the upper Ohio River Basin to their present southerly direction. Later, Wisconsinan glaciers contributed large volumes of outwash to the Ohio River and its glaciated tributaries, forming the terraces and floodplains analyzed in this study.

Early research focused on the complex history of the Ohio River and the terrace levels attributed to the Pleistocene glacial and interglacial stages. Prior to the Illinoian glaciation, the ancestral Ohio River basin was

drained by two small tributaries flowing in opposite directions from a drainage divide near New Martinsville (Leverett, 1902; 1939; Stout and Lamb, 1938; Stout and others, 1943; Tight, 1903; White, 1896). Each of these rivers generally followed the path of the present Ohio River Valley through the study area. The ancestral Steubenville River flowed north to the ancient Pittsburgh River of the Erie Basin at Beaver, Pennsylvania (fig. 1); the ancestral Marietta River flowed south to the Teays River system of the Mississippi Basin (Stout and others, 1938). According to Leverett (1902; 1939), Stout and Lamb (1938), Stout and others (1943), Tight (1903), Cross and Schemel (1956), and White (1896), at least two pre-Wisconsinan glaciations dammed the north-flowing river just north of Beaver, Pennsylvania. Highly weathered terraces (higher than those in the study area--see Appendix I) at greater than 106 m (349 ft) a.l.w. at East End (suburb of East Liverpool) and Wellsville, Ohio contain crystalline rocks (cobbles, and gravels) attributed to outwash from one or more pre-Illinoian glaciations (Lessig, 1961a). The presence of less-weathered Illinoian gravel in terraces at 71 m (230 ft) a.l.w. at East End (Lessig, 1959a) descending to approximately 54 m (175 ft) a.l.w. by Parkersburg (Jacobson, 1985; 1988--see Appendix I), indicate that the drainage divide at New Martinsville was breached before the Illinoian glaciation. The Ohio River roughly followed its present path at this time.

During the Wisconsinan, the Ontario-Erie lobe of the Laurentide Ice Sheet advanced southwestward into the Erie Basin (Fullerton, 1986). The Grand River sublobe spread over the Allegheny Plateau of northwestern Pennsylvania and northeastern Ohio during both the early (Altonian) and late (Woodfordian) substages (fig. 2) of the Wisconsinan Glaciation (White, 1982; White and Totten, 1985). The Killbuck sublobe (and later during the Woodfordian, the Cuyahoga sublobe) covered north-central Ohio (White, 1982), and the Scioto sublobe covered central Ohio (Goldthwait and others, 1961) at this time.

From approximately 79,000 to 65,000 yr. B.P. (Fullerton, 1986), the late Wisconsinan advance deposited the Titusville Till (Table I). The Titusville Till of the Grand River sublobe was deposited 13 km (8 miles) from the West Virginia border on Little Beaver Creek in Ohio, (White, 1982) and 48 km (30 miles) from the West Virginia border on Beaver River in Pennsylvania (figure 2; Shepps and others, 1959). Titusville Till was deposited by the Grand River sublobe at least 260 km (160 miles) from the mouth of the Muskingum River but its correlative till units were deposited by the Scioto sublobe as close as 129 km (80 miles) from the mouth of the Muskingum River (Goldthwait and others, 1961).

After an approximately 42,000 year interglacial stage (fig. 3), correlated with the Farmdalian by White (1982), the Grand River sublobe readvanced during the late Wisconsinan.

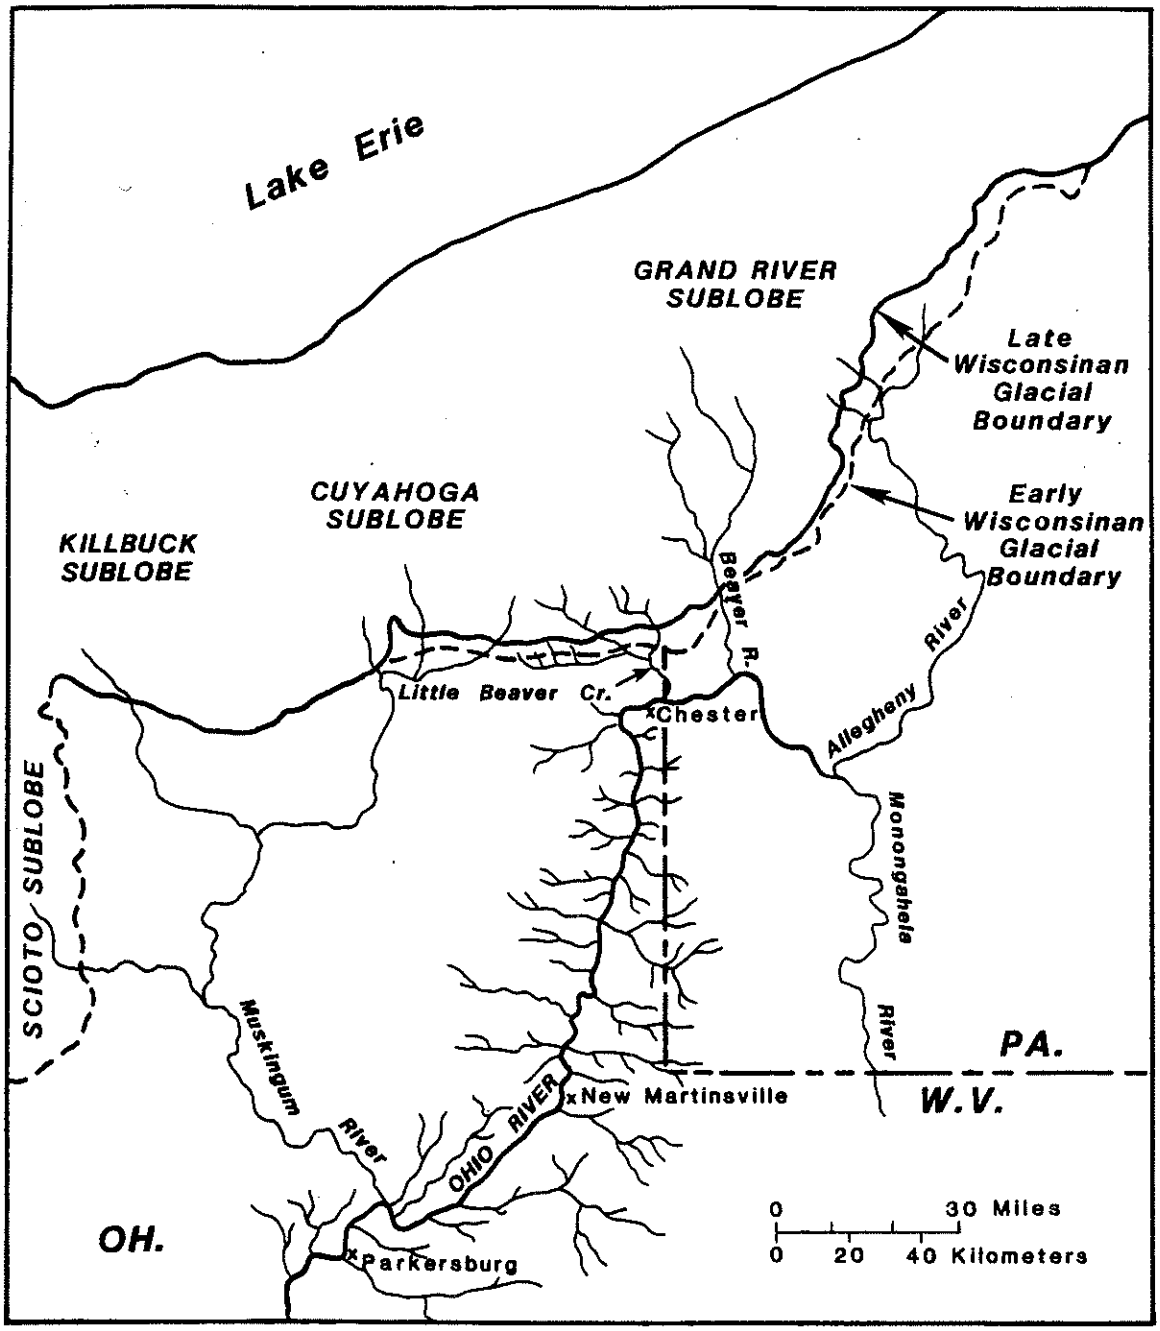

Figure 2. Glacial sublobes. Maximum extent of glacial sublobes during the early Wisconsinan (Altonian) advance and the late Wisconsinan (Woodfordian) advance (adapted from White, 1982, plate 1; Goldthwait and others, 1961; and Pennsylvania Geological Survey, no date).

TABLE I: TIME-CHART OF PLEISTOCENE AND HOLOCENE EPOCHS

EPOCH	GLACIAL AND INTERGLACIAL STAGES	TIME SCALE (yr. B.P.) *
HOLOCENE		Present 10,000
PLEISTOCENE	Late Wisconsinan	35,000
	Farmdalian	65,000
	Early Wisconsinan	79,000
	Sangamonian	132,000
	Illinoian	302,000
	Pre-Illinoian	1.6 m.**

* Dates from Fullerton (1986)
** m. = million

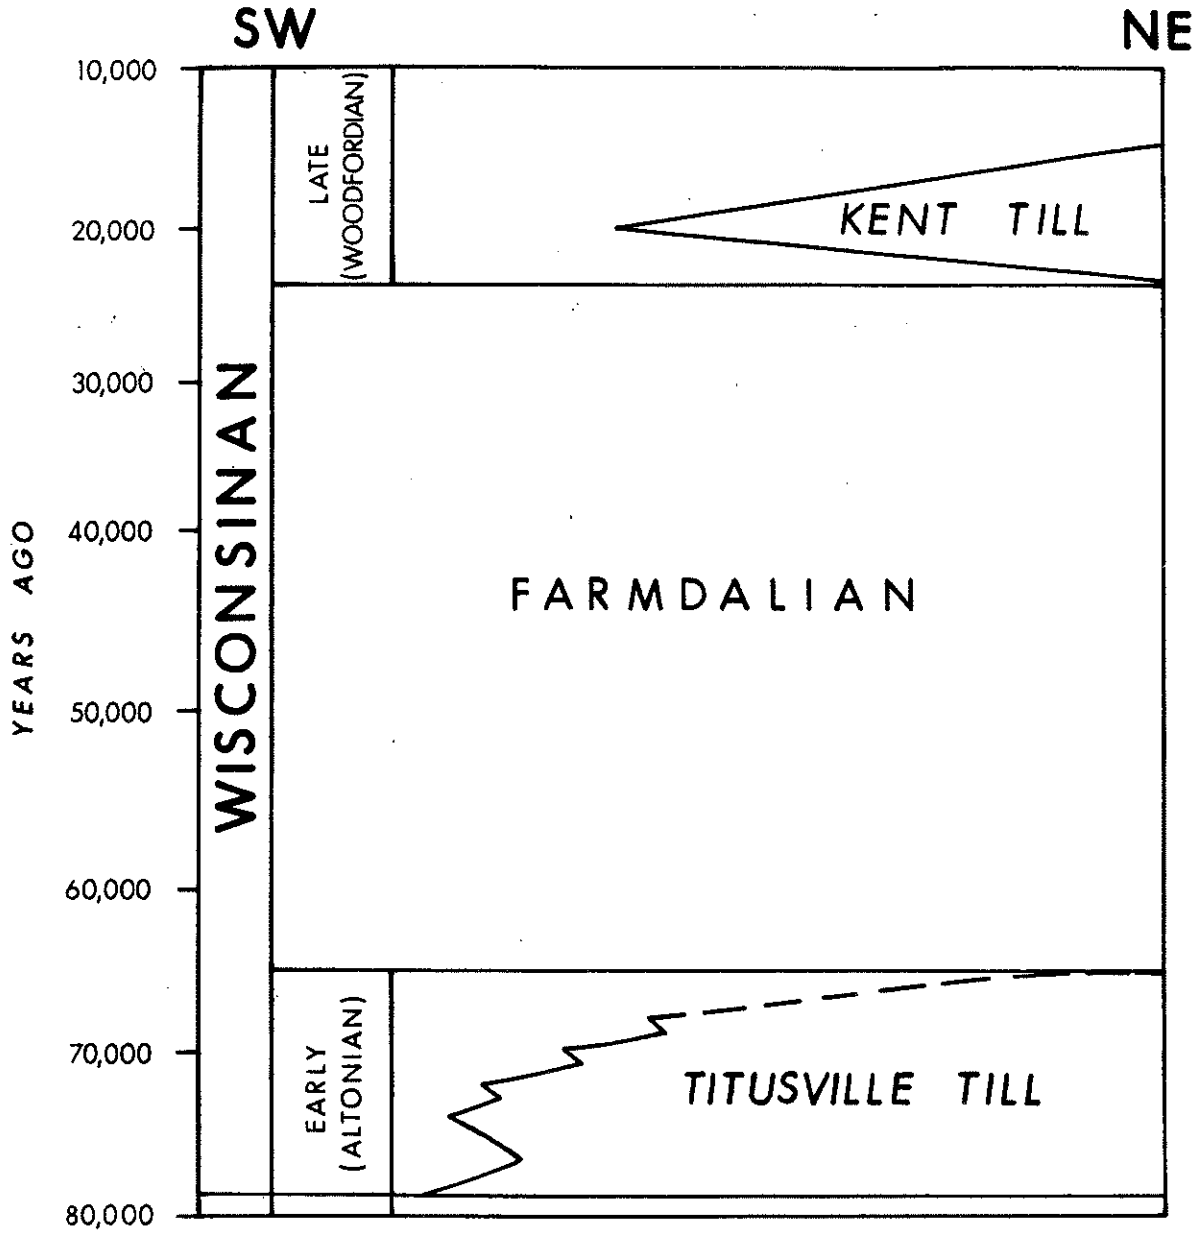

Figure 3. Time scale of Wisconsinan tills of the Grand River sublobe. Thickness of till wedges indicate relative time duration (after White, 1982; dates from Fullerton, 1986).

A thin veneer of Kent Till (dated to range from 23,000 to 16,000 yr. B.P. by Fullerton, 1986) was deposited over the Titusville Till (White, 1982). The Kent advance, not as extensive as the Titusville advance, deposited till within 19 km (12 miles) of West Virginia, figure 2 (White, 1982). Equivalents to the Kent Till were deposited near the early Wisconsinan drift border in the Cuyahoga, Killbuck and Scioto sublobes (White 1982; Goldthwait and others, 1961).

During Altonian and Woodfordian events, the Upper Ohio River system served as an outlet for large volumes of water and sand and gravel outwash transported from as far north as the Canadian Shield, at least 400 km (250 miles) distant. Outwash deposits aggraded in the valley of the Ohio River and its northern tributaries. At least 45 m (147.5 ft) of sand and gravel was deposited at Georgetown, Pennsylvania, at the mouth of Little Beaver Creek. The Allegheny River (64 km, 40 miles, upstream of the West Virginia border), Beaver River (24 km, 15 miles, upstream of the border), and Little Beaver Creek (at the border), drained the Grand River sublobe. All four sublobes were drained by the Muskingum River (fig. 2). The Muskingum River drains into the Ohio River 213 km (132 miles) downstream from Little Beaver Creek, at Marietta, Ohio.

TERRACE CORRELATIONS

Previous correlation of the early-and late-Wisconsinan outwash terraces of the Ohio River and its glaciated tributaries are limited. Terraces have been correlated in Beaver County, Pennsylvania and adjacent Columbiana County, Ohio. Lessig (1959b; 1961a; 1961b) distinguished Illinoian and Wisconsinan outwash terraces of Little Beaver Creek and its tributaries based on degree of soil development, depth of carbonate leaching, and base saturation of the B horizon. No radiocarbon control was available for the terraces at that time. By tracing the terraces of Little Beaver Creek from its mouth to the till margins, Lessig (1961a; 1961b) correlated the Ohio River terraces of 226 m (740 ft) a.s.l. (31 m or 100 ft a.l.w.) at East End, Ohio and 232 m (760 ft) a.s.l. (37 m or 120 ft a.l.w.) at Georgetown, Pennsylvania to the Illinoian (Titusville) Till, and the 213 m (700 ft) a.s.l. (18 m or 60 ft a.l.w.) terraces at East End to the Wisconsinan (Kent) Till. White and Totten (1965), later reassigned the Titusville Till to the early Wisconsinan and the Kent Till to the late Wisconsinan glaciations. White (1982) correlated terraces at 226 m (740 ft) a.s.l. (18 m or 60 ft a.l.w.) at East End, Newell, and Waterford Park (Arroyo) to the Titusville Till. White and Totten (1985) continued the Ohio River terrace correlation further downstream to include all of Columbiana County, Ohio (fig. 4) and some adjacent parts of West Virginia. Later, Jacobson

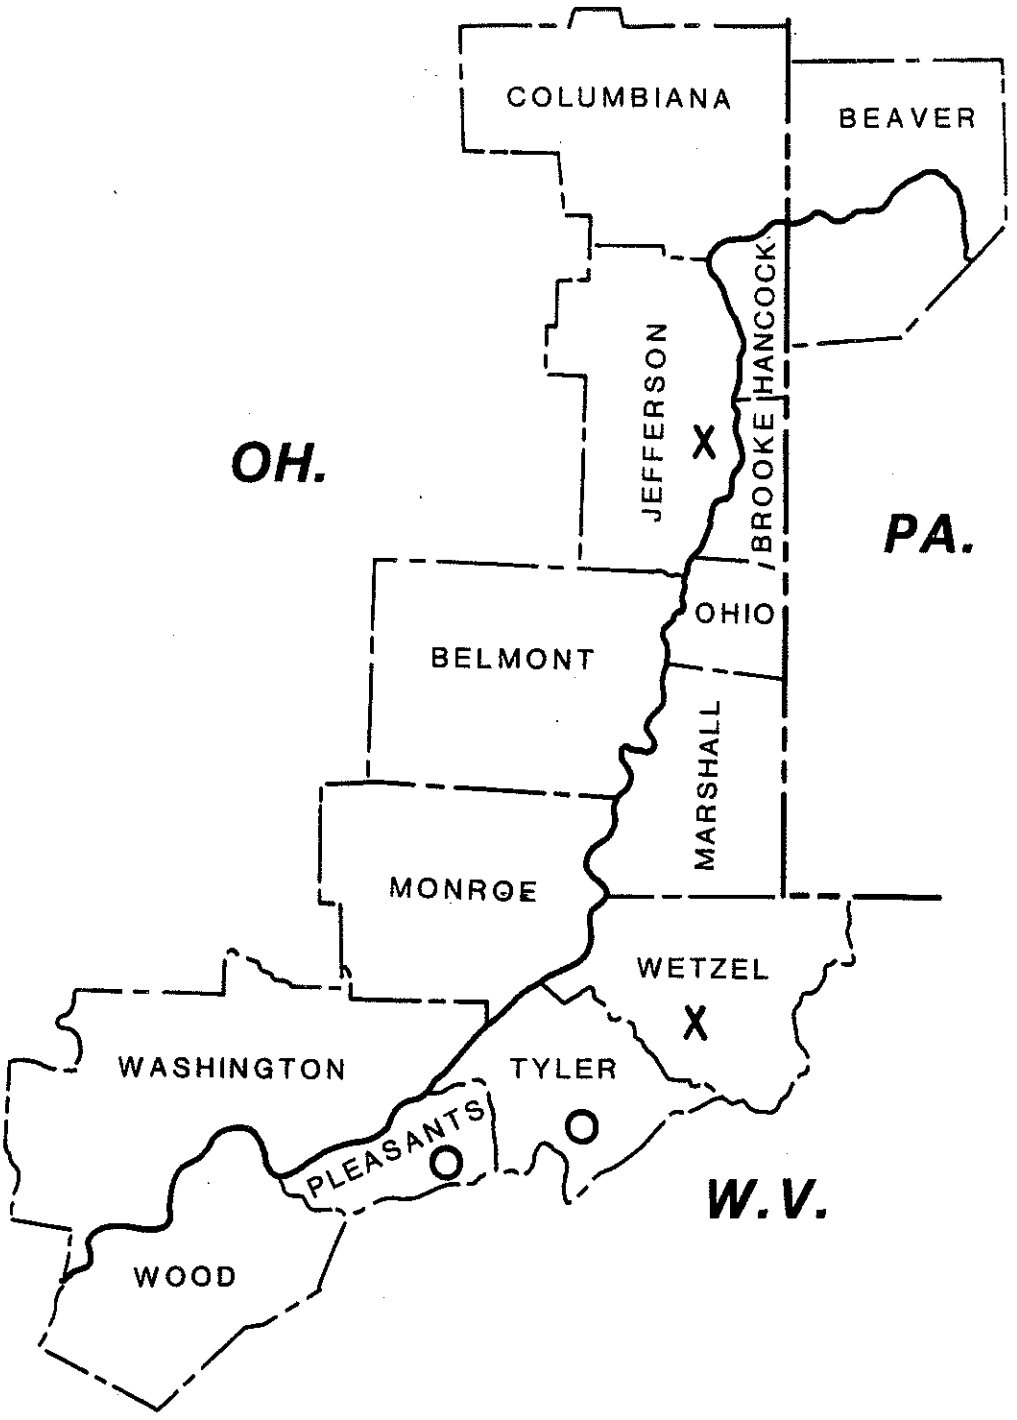

Figure 4. Modern U.S. Department of Agriculture Soil Conservation Service County Soil Surveys (as of 1988) used for soil series names in the study area. X = soil maps in progress in the study area (as of 1988), O = soil maps in progress not in the study area.

(1985) correlated the Woodfordian through the pre-Illinoian Ohio River surfaces upstream of Middle Island Creek (river km 245, mile 152) based on his study of soils along Middle Island Creek, Lessig's research, and U.S. Department of Agriculture (U.S.D.A.) Soil Conservation Service county soil surveys. Jacobson (1988) later continued these correlations downstream to Parkersburg, Appendix I. In the author's preliminary correlation of the Ohio River surfaces along West Virginia's northern panhandle, the eight surfaces of this study were combined as one terrace and one floodplain (Simard and Kite, 1986). The author later segregated these two surfaces into two terraces and one floodplain (Simard, 1987; Simard and Kite, 1987).

Farther south, in Wood County, Fonner (1980) described the soils and stratigraphy of Blennerhassett Island deposits and assigned them relative dates. Later, Fonner (1982) described the stratigraphy of a sand and gravel pit in Boaz, West Virginia (fig. 1) where a mammoth bone dated as 13,510 $\pm$ 270 yr. B.P. (SI-5480) was found.

Previous work on the Muskingum River is limited. Hubbard (1954) used degree of weathering to interpret sand and gravel terraces located 53 to 76 river km (33 to 47 miles) north of the mouth of the Muskingum River as Wisconsinan in age. Root and others (1961) correlated three terraces within the till boundaries at several of the headwaters of the Muskingum River (at least 90 km or 56

miles from its mouth) as Illinoian, early Wisconsinan, and late Wisconsinan. White (1982) later changed the correlation of the so-called Illinoian Till of the northern part of the Scioto sublobe to early Wisconsinan. Otherwise, terraces on the Muskingum River have not been correlated or dated.

In summary, published works indicate that early- and late-Wisconsinan glaciations in Pennsylvania and Ohio created the terraces of the Ohio River. Glacial meltwater drained through Allegheny River, Beaver River, Little Beaver Creek, and Muskingum River to the Ohio River. The degree of weathering of the deposits and development of soils has been used to correlate terraces to the early-and late-Wisconsinan glacial advances. However, these studies lack good radiocarbon dating control.

CHAPTER 3

METHODOLOGY

FIELD METHODS

This thesis grew out of a West Virginia Geological and Economic Survey project to determine West Virginia's land-based Ohio River sand and gravel resource potential for the construction industry. The lower (below 40 m or 130 ft a.l.w.) terraces and floodplains rather than the higher (above 40 m or 130 ft a.l.w.) terraces were examined during the project because their larger size and relatively unweathered deposits make them an excellent sand and gravel resource for the construction industry. The project included taking bulk samples at terrace sites, testing samples for suitability as highway aggregate (run by West Virginia Department of Highways, Charleston), mapping landform surfaces, plotting core hole and well locations, recording stratigraphy on modified strip logs, and calculating inferred resources. A West Virginia Geological and Economic Survey Report will include all of this information plus a summary of the affect of geologic history on the resource potential of the deposits, based on information from this thesis (Simard, in preparation). This thesis is a more detailed study of the stratigraphy, the facies of the deposits, and the geologic history of the surfaces. To more completely correlate the surfaces in West

Virginia, the study area was extended to Wisconsinan tills in Ohio (upstream on Little Beaver Creek), to the reach of Muskingum River near its mouth (in Ohio), and to the reach of Beaver River near its mouth (in Pennsylvania).

Field work began in the summer of 1985 and ended in the fall of 1986. The location of terrace scarps and flats, and bedrock contacts were recorded while reconnoitering the area. Terrace deposits were examined at high walls in sand and gravel pits, at small, hand dug exposures, or with a 1 m (3 ft) by 2.5 cm (1 inch) soil auger (see Appendix II for locations). The location and extent of outwash, overbank alluvium, tributary alluvium, eolian, and colluvium deposits were recorded on U.S.G.S. 7.5-minute quadrangle field maps. Deposits at borrow pits and abandoned or active sand and gravel pits were examined in more detail and sampled for analysis. The pits are located on terraces because sand and gravel deposits are thicker there than on the floodplains and therefore, more economically important. Eight of the 11 sample localities were on terrace S5 (the sixth surface above the river), one was on terrace S7 (at the same level as a segment of S5), and the other two were on terrace S4 (the fifth surface above the river).

Channel samples were taken from a cleaned pit face every 1.5 m (5 ft) or at each change in stratigraphy for sand and gravel according to Boellstorff's (1978) scheme, and within each horizon for soils. One continuous, vertical sand and

gravel sample was seldom taken at a sample site due to steepness (and instability) of pit faces or scree piles too large to be removed by a hand shovel. To work around these problems, samples were taken in offset vertical segments. The sampling process began at the best-exposed pit face at the top of the deposit. The pit face was sampled from the top downward until a scree pile too large to be removed was reached or the face was too steep for safety or accessibility. The height at the bottom of this sampled segment was traced, by leveling or following a marker bed, to the top of a lower, well-exposed pit face. This, and subsequent lower pit faces, were sampled in the same fashion until a vertical composite sample of the site was complete.

Coarse-grained soils were described by using standard American Society for Testing and Materials (1966) methods for description of soils. Each coarse-grained sample description included: depth, sediment name by main particle size constituent, sorting, maximum particle size, size distribution in estimated percentages, grain shape, mineralogy, moist Munsell color (Kollmorgen Corporation, 1975), estimated moisture content, natural density, structure, reaction to 5% dilute HCL, and environment of deposition. Fine-grained soils were described using Soil Survey Staff (1951) standard methods. Each fine-grained sample description included horizon name, depth, moist Munsell color (Kollmorgen Corporation, 1975), texture,

structure, consistency, presence and description of clay films, mottling, and boundary.

CORRELATION METHODS

Field and published information were combined to correlate different surfaces. Eight correlated surfaces were numbered S0 through S7. Floodplain and terrace surfaces were mapped on the most recent (1980 through 1986) 7.5-minute series U.S.G.S. quadrangle maps (see Appendix III) by morphology, lithology, stratigraphy, degree of soil development, and frequency of flooding. The maps had 20 ft contour intervals with some supplemental 10 ft contours. A longitudinal profile of the surfaces (fig. 5) was constructed by plotting the following: elevation and longitudinal extent of the most prevalent surface of each level on both sides of the river and the islands, maximum flood of record (Grover, 1938; Smith and Stratton, 1955), and pre-dam low water river level (U.S. Army Corps of Engineers, 1929a-1929g; 1930a-1930c). The surfaces were correlated on the longitudinal profile by drawing lines to connect surfaces with the same: frequency of flooding, elevation a.l.w. (keeping in mind that progressive downstream change might occur), and soil development.

To aid in correlating surfaces in West Virginia, the longitudinal profile of the Ohio River was extended to the mouth of Beaver River. Longitudinal profiles of the surfaces

were also constructed for a limited distance along glaciated tributaries (figs. 1 and 6). The tributary profiles include: (1) the 10 km (6 miles) upriver from the mouth of Beaver River, (2) the 18 km (11 miles) upriver from the mouth of Little Beaver Creek to the Titusville and Kent Tills in the Grand River sublobe, and (3) the 16 km (10 miles) upriver from the mouth of the Muskingum River.

Along with field information, several different map sources were used for correlating the floodplain and terrace surfaces. The main map source was the topography shown on 7.5-minute series quadrangles. Additionally, U.S.D.A. Soil Conservation Service county soil surveys (see Chapter 4 for listing) provided information of soil development and stratigraphy for the upper 1.8 to 6 m (6 to 20 ft) of sediment. Core logs from early 1900's lock and dam construction (U.S.G.S. unpublished data, Morgantown, West Virginia), water wells (U.S.G.S. unpublished data, Morgantown, West Virginia), oil and gas well logs (West Virginia Geological Survey in-house files), and private companies provided stratigraphic information to the top of bedrock. Also, the 1956 edition of the 7.5-minute series quadrangles in Arkle and others (1967) sand and gravel resource project identify now defunct sand and gravel pits, his sample sites, less disturbed landforms, and 10 ft supplemental contours not found on some of the more recent maps. The 15-minute series maps (1902 to 1942 editions)

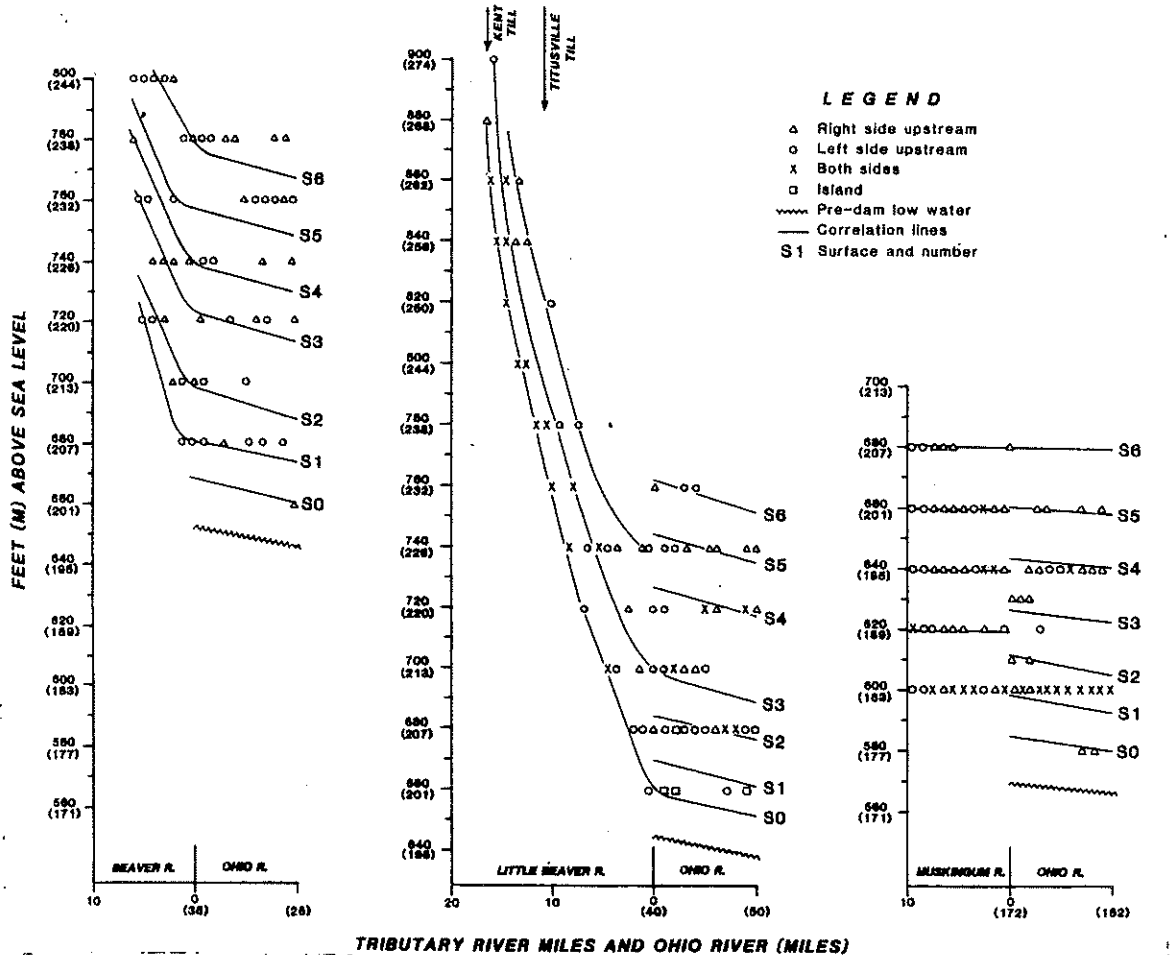

Figure 6. Limited longitudinal profiles of terraces and floodplains of the glaciated tributaries and the Ohio River. S6 and S5 are early Wisconsinan terraces, S4 and S3 are late Wisconsinan terraces, and S2, S1, and S0 are Holocene floodplains.

were consulted for an overview on a smaller scale. Where available, 5 ft contour river channel maps (U.S. Corps of Engineers 1929a-1929g; 1930a-1930c) were used for detailed correlations. These maps included all of the floodplains and some of the lower terraces. Limited use of stereoscopic aerial photographs helped differentiate surfaces not obvious on the other map sources.

LABORATORY METHODS

Samples collected in the field were analyzed in the laboratory to verify field data. Samples from 11 terrace profiles were analyzed to determine soil and sediment characteristics. Particle-size distributions of 85 samples were determined by dry-sieve and pipette methods (Appendix IV). Munsell color (Kollmorgen Corporation, 1975) of wet silt and clay was measured while particles were suspended in a water-filled cylinder during pipette analysis.

Pebble counts of the gravel size common to all sampled coarse deposits, the 12.7 to 6.35 mm (0.5 to 0.25 inch) and 4.00 to 2.00 mm (0.16 to 0.08 inch) size gravels, were done for 20 samples (see Appendix V for results). The lithology of all of the 6.35 mm and about 200 of the 2.00 mm size gravels per sample were counted for a representative sample (Griffiths, 1967). Lithology was identified by hand specimens, which were broken, if necessary, for a fresh surface and examined with a 10 power hand lense. Limestone gravels were identified from efforvescence with the

application of a 5% hydrochloric acid solution. Roundness and sphericity measurements were limited to the 6.35 mm gravels because the 2.00 mm gravels were too small to be categorized by hand specimens. Roundness was estimated by comparing the gravels to a roundness chart from Krumbein (1941) whereas sphericity was estimated from a sphericity chart by Krumbein and Sloss (1963).

Computer programs (Appendix VI) were used to calculate grain-size distributions and statistical moments. The grain-size distributions and statistical moments were generated as data sheets for individual samples. Grain-size distributions were also plotted as grain size versus depth for each site.

CHAPTER 4

LANDFORMS, DEPOSITS, AND RADIOCARBON DATES

LANDFORMS

The landforms of the Ohio River and its glaciated tributaries (Beaver River, Little Beaver Creek, and Muskingum River) were studied in detail for their vertical and downstream changes in stratigraphy, height a.l.w., and soil development. Soil development is emphasized because it is a relative method of dating surfaces with no radiocarbon control. Each surface level, drawn in figures 5, and 6, represents the most extensive levels shown on 7.5-minute topographic maps. The contours on this scale (1:24,000) were mainly at 20 foot intervals with some supplemental 10 foot intervals. A limited number of 1:7,200 scale maps with a 5 foot contour interval were available for some of the floodplains (U.S. Corps of Engineers 1929a-1929g; 1930a-1930c). For the terraces, small segments and surfaces separated by less than 10 feet could not be detected on the 1:24,000 scale. Therefore, more than the eight levels described in this study may exist, but the data limits the precision of the interpretation.

Eight fluvial surfaces have been identified in the two reaches of the upper Ohio River Valley from the mouth of Beaver River, Beaver County, Pennsylvania to Paden City and from the northern end of Wood County, to Washington Bottom,

West Virginia. The levels, designated as S0 through S7, include three floodplains and five terraces, two of which (S5 and S7) occur at the same level (fig. 5). S7 is an older terrace remnant (probably pre-Wisconsinan) which occurs at the same level as a segment of S5 (early Wisconsinan) from the Weirton abandoned channel to Beech Bottom. None of the surfaces are continuous on both sides of the river (fig. 7). Surfaces are denoted by height a.l.w. on figure 8, in order to replicate conditions before water level was artificially raised by dams. The first set of C.O.E. dams, built in the early 1900's, raised normal pool water level on the Ohio River approximately 1 m (3.3 ft) to 6 m (19 ft). These dams have been replaced by fewer but larger dams that raised normal-pool water level 2.4 to 10.4 m (8 to 34 ft) a.l.w. In places, the raised water levels cover S0 and S1 surfaces (fig. 5).

U.S.D.A. Soil Conservation Service county soil survey reports used for soil series names, soil distribution, and the upper 1.8 to 6 m (6 to 20 ft) of stratigraphy include the following (from north to south): Beaver and Lawrence Counties, Pennsylvania (Smith, R. V., 1982); Columbiana County, Ohio (Lessig and others, 1968); Ohio, Brooke, Hancock Counties, West Virginia (Ellyson and others, 1974); Belmont County, Ohio (Rubel and others, 1981); Marshall County, West Virginia (Kunkle and others, 1960); Monroe County, Ohio (Hayhurst and others, 1974); Wetzel County, West Virginia

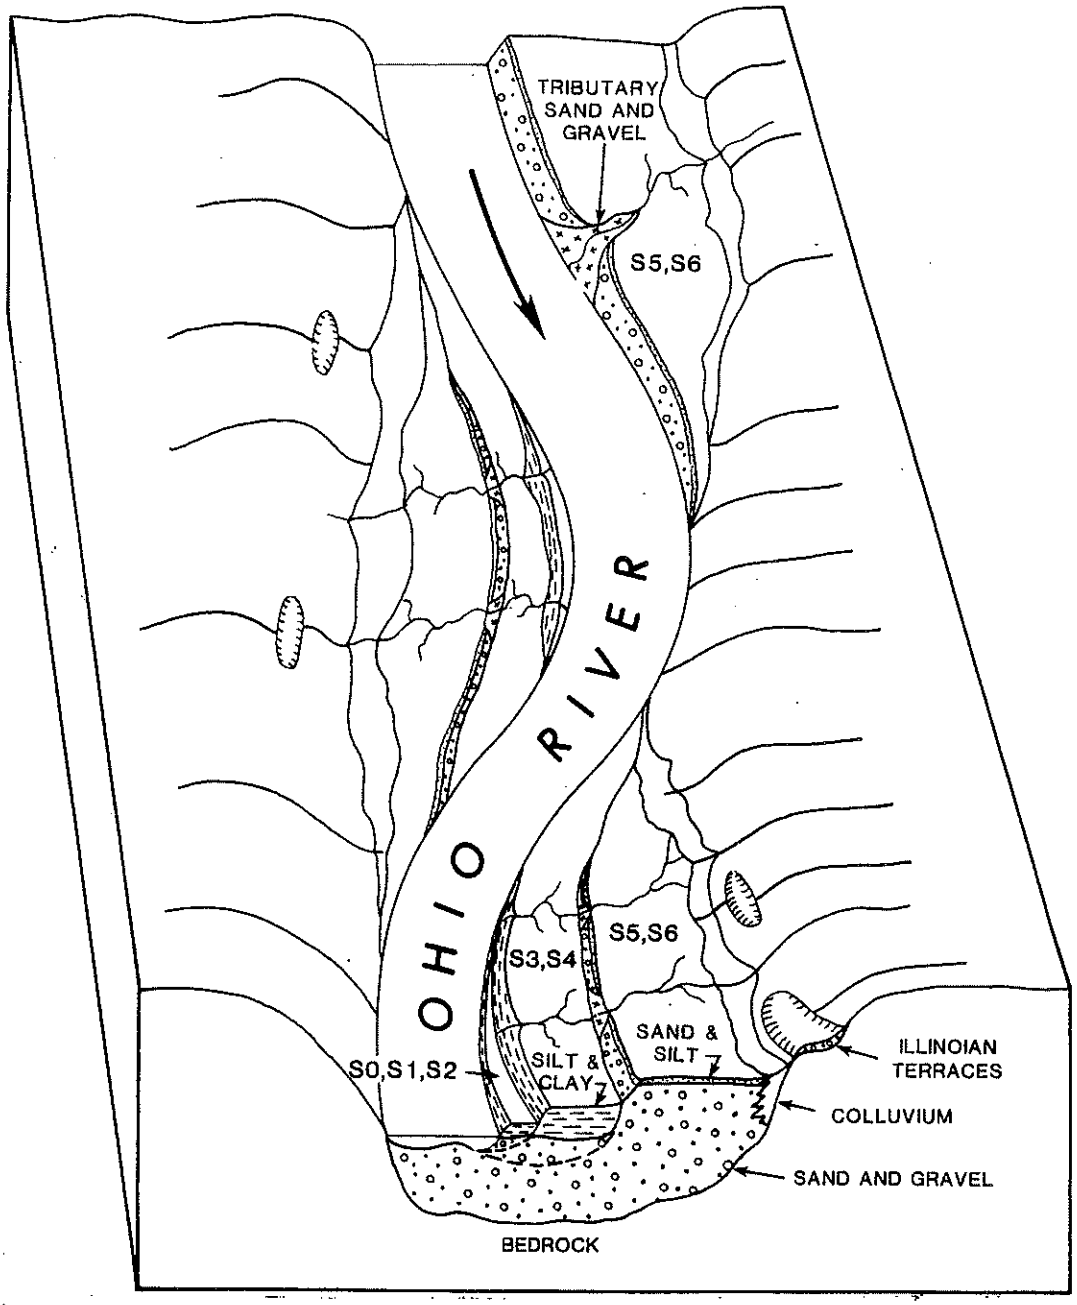

Figure 7. Model block diagram (not to scale) of alluvial surfaces and facies of the Ohio River Valley. S5, S6 represent early Wisconsinan terraces, S3, S4 represent late Wisconsinan terraces, and S0, S1, S2 represent Holocene floodplains. The five facies are labeled as: (1) sand and gravel (coarse-grained Ohio River alluvium or outwash), (2) tributary sand and gravel, (3) colluvium, (4) silt and clay (fine-grained Ohio River alluvium or overbank sediment), and (5) sand and silt (eolian).

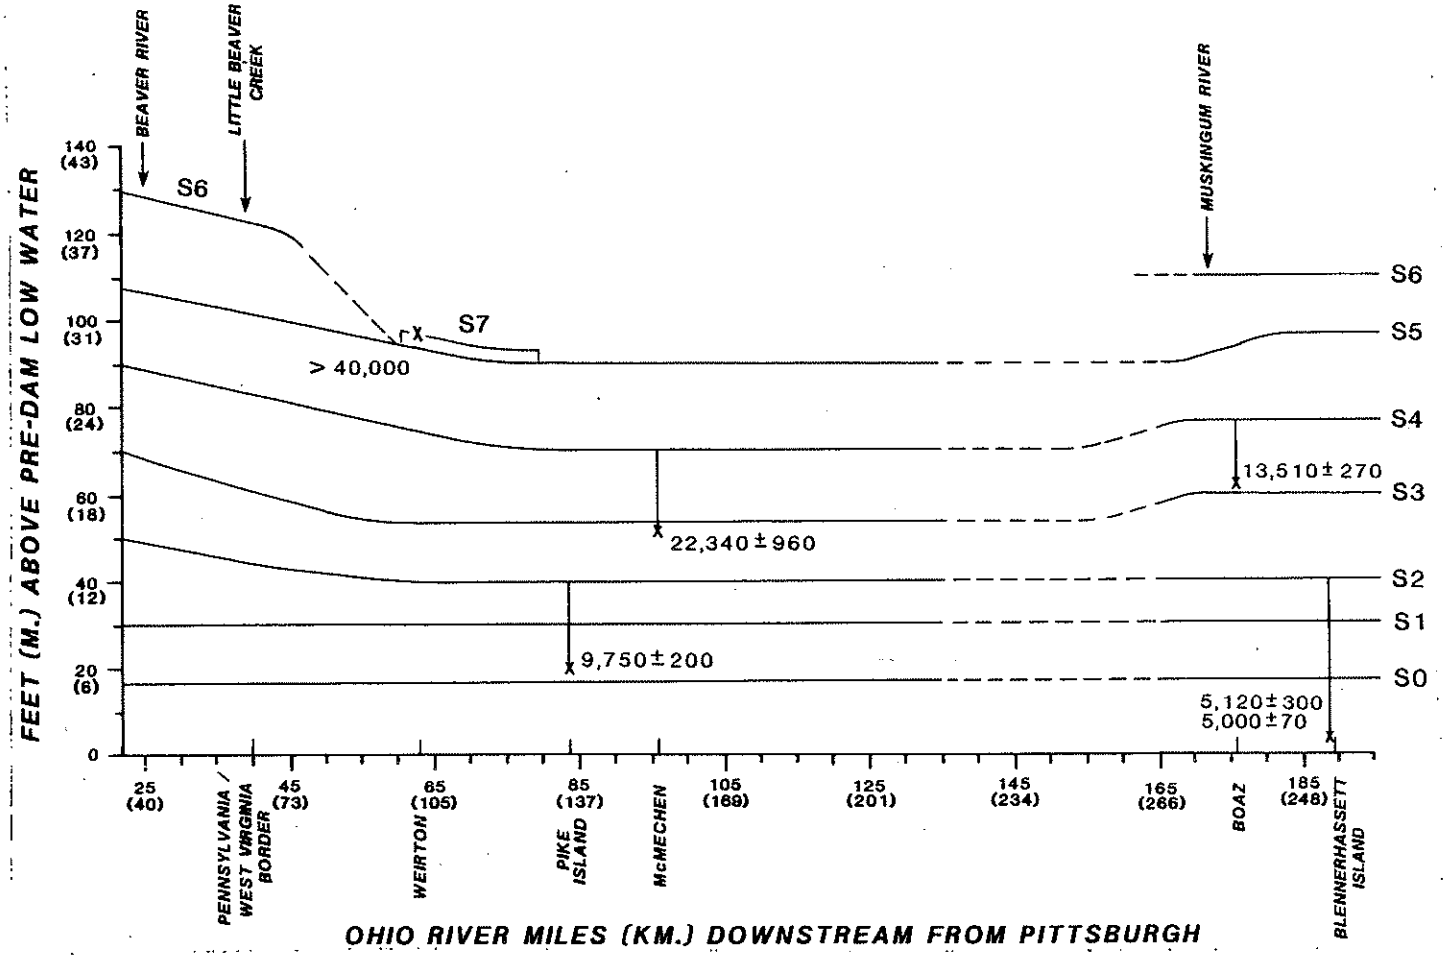

Figure 8. Longitudinal profile and radiocarbon dates of Ohio River Valley surfaces plotted on pre-dam low water base level. Terrace S7 is probably Sangamonian, terraces S6 and S5 are early Wisconsinan, terraces S4 and S3 are late Wisconsinan, and floodplains S2, S1, and S0 are Holocene. Radiocarbon dates plotted (x) at relative depth below surface.

(Mara, in progress); Wood and Wirt Counties, West Virginia (Ellyson and others, 1970) Washington County, Ohio (Lessig and others, 1977). Figure 4 shows county locations and the soil surveys used in this study, and Table II summarizes soil information, and stratigraphy of each surface.

Surfaces S0 through S6 are underlain by a broad, shallow, roughly U-shaped valley (fig. 9), as shown by core logs at Georgetown, Pennsylvania (river km 63, mile 39) and Arroyo (river km 81, mile 50) (I. Maurer, 1988, personal communication--oil and gas well numbers in Appendix II). These core logs provide the most complete valley cross-section used in this study (although proprietary information from engineering firms exists). Cleason Smith (personal communication, 1984) confirmed the broad, U-shape of the valley farther downstream. Anomalies in the channel morphology occur under S5 at Follansbee and S7 at Beech Bottom (fig. 10). The bedrock floor at Follansbee (river km 113, mile 70) forms an approximately 0.5 km (0.3 mile) wide bench at an average elevation of 195 m (640 ft) a.s.l. (see Appendix II for oil and gas well numbers). This elevation is about 21 m (70 ft) higher than the bedrock floor underlying the S0 through S6 channel (represented in figure 10 by S1) 13 km (8 miles) upstream at Weirton (D'Appolonia and others, 1967, fig. 1). The bedrock floor underlying S7 was exposed at Beech Bottom (13 km or 8 miles downstream from Follansbee) at approximately 198 to 201 (650 to 660 ft) a.s.l., as

KEY TO HEADINGS: Thickness of sediment from listed County Soil Surveys, core logs, and sample sites (see Appendix II). S7 information from Weirton and Beech Bottom sites (not surveyed in County Soil Surveys). Soil information from County Soil Surveys listed. SN = sand, SI = silt, CL - clay, S & G = sand and gravel (alluvial grain sizes listed in table in arbitrary order). County (N to S) = counties with each soil series listed from north to south. County Codes: BE (P) = Beaver, Pennsylvania; CO (O) = Columbiana, Ohio; BL (O) = Belmont, Ohio; MN (O) = Monroe, Ohio; WA (O) = Washington, Ohio. West Virginia Counties: HN = Hancock; BR = Brooke; OH = Ohio; MR = Marshall; WE = Wetzel; WO = Wood.

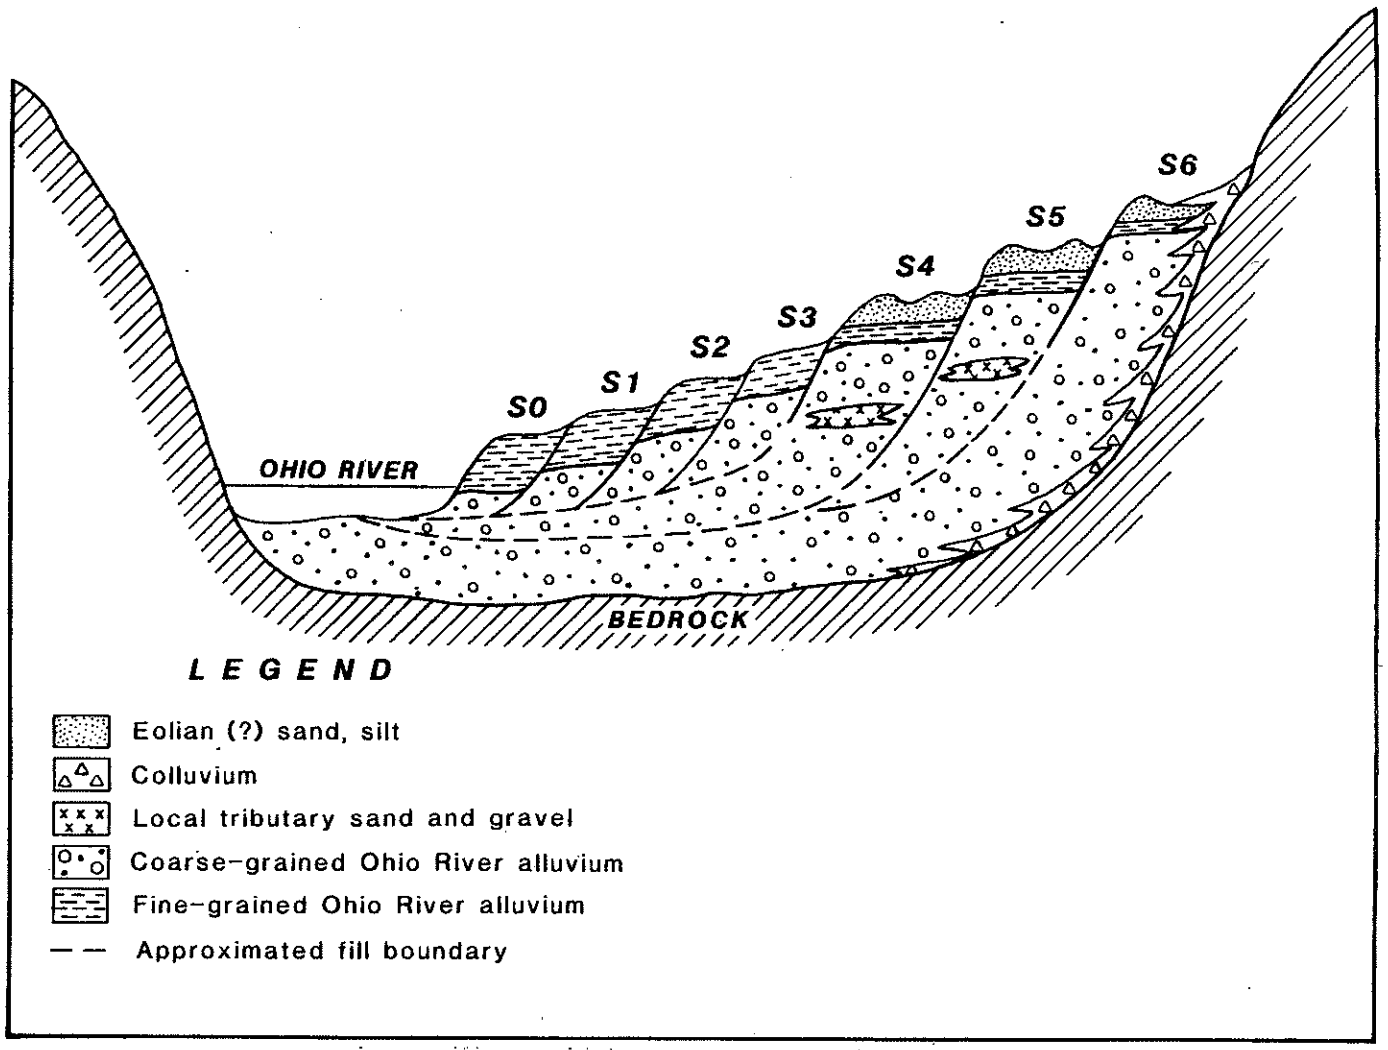

Figure 9. Idealized model cross-section (20 times vertical exaggeration) of Wisconsinan and Holocene surfaces and facies. S6 and S5 are early Wisconsinan, S4 and S3 are late Wisconsinan, S2, S1, and S0 are Holocene. Thickness of deposits shown as averages (from available core logs listed in Appendix II).

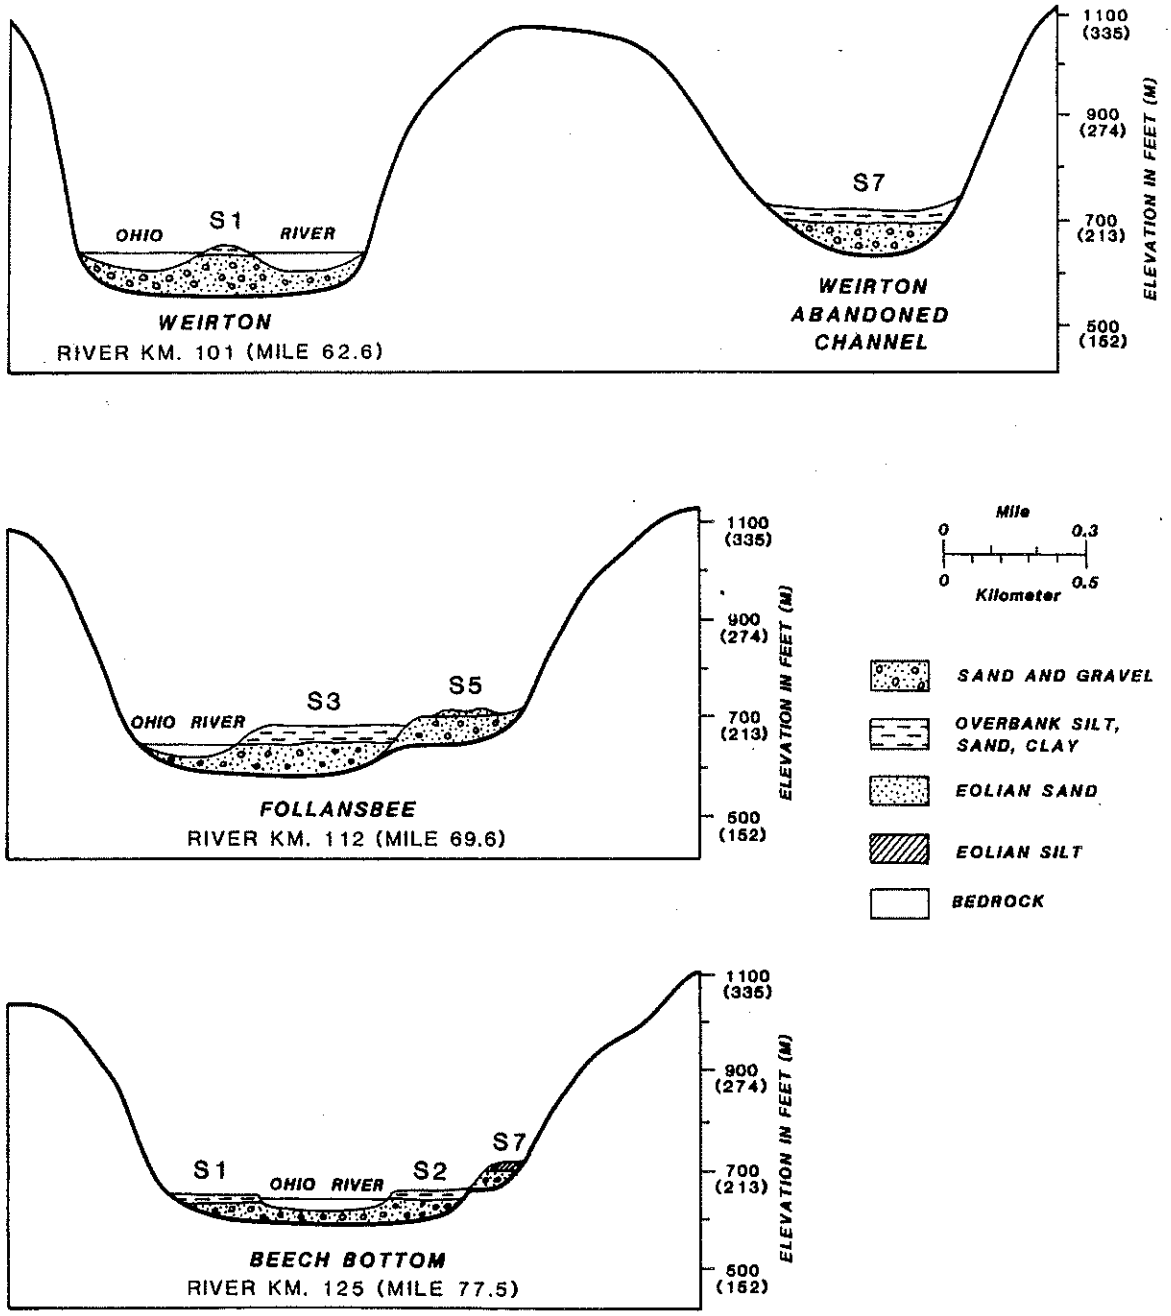

Figure 10. Ohio River Valley cross-section of elevated bedrock floor under terraces S7 and S5. Cross sections are at indicated mile markers.

estimated from a 7.5-minute topographic map. The abandoned channel at Weirton (13 km or 8 miles upstream from Follansbee) also has an elevated bedrock floor of roughly 195 m (640 ft) a.s.l. (D'Appolonia and others, 1967, fig. 1).

Surface 0 (S0), the surface closest to the river is located 5 m (16 ft) or less a.l.w. throughout the study area (fig. 5). S0 is a typically narrow floodplain that is inundated by water several times a year (where it is above normal-pool level of the present C.O.E. locks and dams, fig. 5). Surface 1 (S1), approximately 4 m (14 ft) higher than S0 or approximately 9 m (30 ft) a.l.w. (fig. 8), is inundated once every three or four years (where it is above normal-pool level of the present C.O.E. locks and dams, fig. 5), as described for the Huntington soil series in Monroe County, Ohio (Hayhurst and others, 1974). Both surfaces maintain their respective heights a.l.w. throughout the study area. S0 is rare in the northern part of the study area because the valley is narrow, but becomes more common below the mouth of the Muskingum River (fig. 5) where the valley is wider. S1, on the other hand, begins on the Ohio River above Beaver River and continues downstream as the most prevalent surface in the valley (fig. 5). S1 is also less continuous in the northern panhandle than in the Wood County area. Beaver River and the Muskingum River have floodplains at the same relative level as S1, whereas Little Beaver Creek has a floodplain at the same relative level as S0 (fig. 6).

Soil formation on S0 and S1 is frequently interruped by scour and the addition of overbank sediment during floods. As a result, soil profile development is limited by the short amount of time since alluvial deposition. Therefore, the soils are poorly developed with no argillic horizons and only a slight difference in color below the surface layer identifying a B horizon (see Table II). Soils are developed to a depth of about 1.5 m (5 ft). The silt, sand, and clay overbank sediment also includes occasional lenses of sand and gravel. Thicknesses of the overbank deposits range from 1.1 to 10.4 m (3.6 to 34 ft), see Table II.

Surface 2 (S2) is a floodplain surface that is occasionally flooded. S2 begins on the Ohio River above Beaver River and continues downstream as the second most prevalent surface. The surface is at approximately 15 m (50 ft) a.l.w. in Beaver County, Pennsylvania, tapers to a height of approximately 12 m (40 ft) by 64 km (40 miles) downstream, and maintains that height to the end of the study area (fig. 8). Beaver River is the only glaciated tributary with a surface at this height (fig. 6). Beaver River and the Ohio River, often have gravel near the surface until river km 72 (mile 45), where 1.2 m (4 ft) of overbank silt, sand, and clay with occasional lenses of sand and gravel mantle the gravel (see Table II). According to water well logs from Wellsburg (river km 119, mile 74) downstream to Paden City and in Wood County (Appendix II), 1.2 to 11.3 m

(4 to 37 ft) of fine overbank sediment (silt, sand, and clay) cover the sand and gravel.

All the soils on S2 are Alfisols. The soils in the sand and gravel are weakly to moderately developed and have Bt (argillic) horizons. Some of the soils in the finer-grained parent material have distinct Bt horizons with weak but definite clay accumulations while others are moderately developed with a Bt and Bx (fragipan) horizon, respectively (see Table II). The Wheeling variant series in Monroe County has a thicker silt cap and is flooded more frequently than the regular Wheeling series, and thus, is considered equivalent to the other soil series on S2.

The Chili series has been correlated in Columbiana County, Ohio to the Wisconsinan advance (Lessig, 1961b). White (1982) later changed the correlation of the Chili series to the late Wisconsinan Kent advance. Lessig traced terrace surfaces of Little Beaver Creek and parts of the northern Ohio River to the limit of the Kent Till as well as studying the terrace soil development. No radiocarbon control was available for the terraces in that area. Kent age gravelly soils (later named Chili series by Lessig and others, 1968) are leached of limestone clasts to a depth of 1.5 to 2.4 m (5 to 8 ft), have combined A and B horizons of 0.8 to 1.2 m (2.5 to 4 ft) deep, and have a "moderate" amount of clay accumulated in the Bt horizon. The late Wisconsinan Chili soils are similar to the early Wisconsinan Negley soils

but are not as well developed or as well weathered (Lessig, 1961b). Soils in other counties on surfaces correlative to Columbiana County surfaces with Chili and Negley series soils (Table II) are not differentiated as early-or late-Wisconsinan, if they are identified as Wisconsinan at all. Lessig's correlations of Ohio River terrace deposits by degree of soil formation (1961b) is the most in-depth study available. Surfaces correlative to those with Chili series in Columbiana County should be late Wisconsinan in age, based on the research by Lessig (1961b), Lessig and others (1968), White (1982), and White and Totten (1985). However, two radiocarbon dates for S2 downstream from Columbiana County show a Holocene age (see Radiocarbon Dates section). The late Wisconsinan Kent age for the Chili series on S3 can be inferred by its position between S4 (radiocarbon dated as Kent-aged) and S2 (radiocarbon dated as very early Holocene-aged). Either Lessig's correlations of Chili series soils cannot be extended downstream or the series is not exclusively confined to Kent-aged surfaces.

Surface three (S3) begins above the mouth of Beaver River and continues downstream as the third most continuous surface (fig. 5). The terrace surface begins approximately 21 m (70 ft) a.l.w. and has lowered to approximately 16 m (53 ft) a.l.w. by river km 97 (mile 60), an elevation it maintains until river km 250 (mile 155) (fig. 8). For the next 32 km (20 miles), it gradually rises 2 m (6 ft) until it

is 18 m (60 ft) a.l.w. at the mouth of the Muskingum River. This height is maintained to the end of the study area. The surface was partially flooded in the record high floods (from the northern end of the study area to river km 185 (mile 115) in 1936 and downstream to the end of the study area in 1913. Floodwaters deposited mud on the surface in Ohio and Marshall Counties, West Virginia (U.S. Corps of Engineers, 1971a; 1971b) and presumably also in the other Ohio River counties. Surface sediment is sand and gravel in Beaver County, Pennsylvania and Columbiana County, Ohio. Farther downstream, from Monroe County, Ohio (river km 113, mile 70) to the end of the study area, core logs and U.S.D.A. Soil Conservation Service soil descriptions reveal 1.0 to 9.8 m (3 to 32 ft) of overbank silt, sand, and clay. Silt (loess?) mantles the surface in Belmont County, Ohio, whereas sand (eolian ?) is the surface mantle in Wood County. S3, with a cap of overbank sediments, can be traced up the Muskingum River as a discontinuous surface (fig. 6).

The soils of S3 have weakly to moderately developed profiles. All have a Bt as the best-developed horizon except for one which has a Bx horizon, and the B and C horizon in the sand deposits (see Table II). Poor soil development in the sand deposit is partly due to the thick, deep, very highly permeable sands not being conducive to soil development rather than a young age (Ellyson and others, 1974).

Although surface four (S4) is not as common as S3, it occurs throughout the river's length. S4 begins on the Ohio River north of Beaver River, where it is joined by a Beaver River terrace of the same level (fig. 6), and continues downstream to the end of Wood County. The Muskingum River also has a terrace at this level. S4 begins at an elevation of approximately 27 m (90 ft) a.l.w. in the north, tapers to approximately 21 m (70 ft) by river km 250 (mile 155), where it gradually rises to approximately 23 m (76 ft) near the mouth of the Muskingum River (fig. 8). It maintains this level to the end of the study area.

S4 is gravelly to the north, in Beaver and Columbiana Counties, and below the mouth of the Muskingum River in Washington County. The coarse deposits are covered downstream by 1.1 to 6 m (3.5 to 20 ft) of alluvial silt, sand, and clay. A core log on S4 at Warwood (river km 138, mile 86) shows 1.9 m (6.3 ft) of silt, sand, and clay and two core logs on S4 at Paden City (river km 317, mile 197) show 3 m (10 ft) of the same sediment (Appendix II). Greater than 1.2 m (4 ft) of sand locally mantle S4 in Ohio, Brooke, Hancock, Marshall, Washington, and Wood Counties. The U.S.D.A. Soil Conservation County soil surveys (see Table II) attribute the sand to wind and water-laid deposits. Only the Wood County soil survey differentiates them by defining water-laid deposits as 1.2 to 1.8 m (4 to 6 ft) of sand with a 3 to 10% slope, and "apparent" wind deposits as greater

than 3 m (10 ft) of fine sand with a 3 to 30% slope. Two of the sample sites, Power and New Martinsville, are on this surface (figs. 1 and 5).

The soils of S4 are the same series as S3 soils with the addition of the gravelly Negley series in Columbiana County. Negley soils also have a moderately developed Bt horizon. The Negley series is characteristic of Little Beaver Creek and Ohio River terraces correlated to the "Illinoian" advance (Lessig, 1961b). White (1982) later changed the correlation of the Negley series to the early Wisconsinan Titusville advance. Titusville age gravelly soils (later named Negley series by Lessig and others, 1968) are leached of limestone clasts to a depth of 5 to 8 m (15 to 25 ft), have a B horizon of 0.9 to 2.4 m (3 to 8 ft), and more clay than the late Wisconsinan Kent age Chili series. The early Wisconsinan Negley series has a similar parent material to the late Wisconsinan Chili series but is more developed and weathered (Lessig, 1961b). The Negley series is the only soil in the U.S.D.A. Soil Conservation Service county soil surveys distinguished as early Wisconsinan. Surfaces correlative to those with Negley series soils in Columbiana County should be early Wisconsinan in age, based on research by Lessig (1961b), Lessig and others (1968), White (1982), and White and Totten (1985). However, two radiocarbon dates for S4 downstream from Columbiana County show a late Wisconsinan Kent age, not an early Wisconsinan Titusville age

(see Radiocarbon Dates Section). One of the dates for S4 (22,340 ± 960 yr. B.P.) is very early Kent (Table I), which suggests that S5 and S6 were deposited prior to the Kent-aged terraces. Therefore, an early Wisconsinan Titusville age can probably be inferred for the Negley series on S5 and S6, but not S4. Either Lessig's correlations of the Negley series soils cannot be extended downstream or the series is not exclusively confined to Titusville-aged surfaces.

Terrace S5 begins on the Ohio River at river km 55 (mile 34) and continues downstream as a common surface (fig. 5). S5 begins at an elevation of approximately 32 m (106 ft) a.l.w. and has tapered to approximately 27 m (90 ft) a.l.w. by river km 121 (mile 75), an elevation it maintains until river km 274 (mile 170). For the next 16 km (10 miles), it gradually rises to 29 m (96 ft) a.l.w. and maintains that level to the end of the study area (fig. 8). Little Beaver Creek and the Muskingum River have surfaces at the same level as S5 (fig. 6).

S5 has the same gravelly surface and soil series as S4 in Columbiana, Beaver, and Washington Counties (Table II) but is capped dowstream by 0.6 to 6 m (2 to 20 ft) of alluvial silt, sand, and clay. Locally, the surface is mantled by 0.7 to 4.6 m (2.5 to 15 ft) of silt and sand. Also, two exposures of approximately 15 m (50 ft) of trough cross-bedded sand are located 13 km (8 miles) upstream from the Muskingum River's mouth just north of the Wood County line.

These thick sand units were probably deposited in a lower energy environment than the sand and gravel deposited farther upstream along West Virginia's northern panhandle. Eight sample sites are on S5: East End (Ohio), Chester, Newell 1 and 2, Arroyo sand, Follansbee sand, Follansbee sand and gravel, and Dilles Bottom (Ohio), see figures 1 and 5.

S6 occurs in two segments of the Ohio River (fig. 8). The first segment begins north of the mouth of Beaver River, where it is joined by a terrace on that tributary, and ends at approximately river km 73 (mile 45) at East Liverpool, Ohio (fig. 5). The level begins about 38 m (123 ft) a.l.w., and gradually declines to about 32 m (105 ft) a.l.w. before disappearing. It reappears at the mouth of the Muskingum River and continues at about 34 m (110 ft) a.l.w. to the end of the study area (fig. 8). The terrace has a gravelly surface in Beaver and Columbiana Counties (see Table II). Below the mouth of the Muskingum River, 1 to 1.5 m (3 to 5 ft) of overbank silt, sand, and clay and 0.7 to 4.6 m (2.5 to 15 ft) of sand of possible eolian origin cover the surface.

Segments of an older surface, S7, are at the same level as S5 from Weirton (river km 103, mile 64) to at least Beech Bottom (river km 126, mile 78), and possibly farther downstream (fig. 8). This reach of the Ohio River does not have any S6 surfaces. S7 is called a separate surface, even though it is at the same level as S5 (fig. 5), because evidence, such as the elevated bedrock floor at Weirton's

abandoned channel and the anomalously well-developed soil profile at Beech Bottom (figs. 1 and 10), suggests that S7 is older than S5. In comparison, a less well-developed soil profile, similar to that of S5, formed in the alluvium overlying the Follansbee elevated bedrock floor. Therefore, the uppermost deposits at Follansbee is probably younger than the S7 deposit.

The elevated bedrock floor is 195 m (640 ft) a.s.l. at Weirton (river km 100, mile 62) (D'Appolonia and others, 1967, fig. 1), an average of 195 m (640 ft) a.s.l. at Follansbee (river km 113, mile 70) (see Appendix II for oil and gas well numbers), and an estimated 198 to 201 m (650 to 660 ft) a.s.l. at Beech Bottom (river km 126, mile 78) where it outcrops below the alluvium (fig. 10). The elevations at Follansbee and Beech Bottom are rough estimates based on measurements of valley-side remnants whereas the Weirton channel elevation is a rough estimate based on a cross-valley profile, so these levels should not be interpreted as a drainage reversal. Weirton's abandoned valley is only half the width of the present Ohio River Valley at its maximum width at Weirton. The bedrock floor underlying S7 is 21 to 27 m (70 to 90 ft) higher than the present Ohio River bedrock floor at Weirton (D'Appolonia and others, 1967, fig. 1).

The bedrock floor underlying the deposits correlated as Illinoian (Jacobson, 1985, fig. 3.5) are at an elevation of 245 m (804 ft) a.s.l. at Globe Hill (16 km or 10 miles

upstream from Weirton) and at 241 m (790 ft) a.s.l. at the terrace scarp at East End (37 km or 23 miles upstream from Weirton) (Lessig, 1959a; 1959b). Again, the bedrock elevations are rough estimates of the channel floor because they are measured at valley-side remnants. These elevations are approximately 40 to 50 m (130 to 164 ft) higher than the S7 bedrock floor at Weirton's abandoned channel, Follansbee, and Beech Bottom. Relative elevations show that the bedrock floor under S7 is lower than, and therefore post-dates the bedrock floor underlying Illinoian alluvium, but pre-dates the bedrock floor underlying S0 through S6.

A comparison of weathering of the alluvium overlying these bedrock floors provides a relative means for dating the deposits. In the Illinoian terrace alluvium at East End and Globe Hill, Canadian Shield erratics were rotten to a depth of 4 m (13 ft) and limestone clasts were completely decomposed and lacking throughout the profile (Lessig, 1959a; 1959b). No alluvial deposits examined in this study were as well-weathered.

An analysis of weathering of the alluvium in Weirton's abandoned channel could not be made in this study due to the lack of exposures because of extensive urban development. However, cobble-sized Canadian Shield erratics were sampled from shovel holes at two terrace scarps. A radiocarbon date of greater than 40,000 yr. B.P. at the interface of the colluvium overlying alluvium (D'Appolonia and others, 1967)

indicates that the alluvium is at least older than late Wisconsinan (see Table I).

Beech Bottom alluvium is less weathered than Illinoian alluvium. The 3.4 m (11 ft) thick silt cap has a thick soil with 0.9 m (37 inches) of well-developed argillic (Bt) horizon and a 1.4 m (55 inch) thick fragipan (Bx). Both the Bt and Bx horizon have moderate prismatic structure. The 7.3 m (24 ft) of sand and gravel underlying the silt contains some poorly cemented sandstones that were oxidized orange and rotten to the point of being broken with only fingers. No rotten sandstones were found at any other sample sites or exposures in this study. Canadian Shield erratics, limestones, and other sandstones were intact although somewhat weathered. Extensive gullying of the S7 segment at Beech Bottom may be a function of its relatively old age. Contour crenulations on 7.5-minute topographic maps indicate similar gullies occur on a surface of the same elevation at Wellsburg, 6 km (4 miles) upstream. The Wellsburg terrace is similar to the Beech Bottom terrace in that it is also a narrow segment against the valley wall and has a thick silt cap overlying sand and gravel. No exposures were available in Wellsburg for a detailed study of the deposits and the bedrock floor elevation is unknown. However, Canadian Shield erratics were obtained from shovel holes at two terrace scarps. Based on a similar degree of erosion of surface silt, the Wellsburg S7 alluvium is probably the same age as

the Beech Bottom S7 alluvium. Using Lessig's (1959a; 1959b) criteria of weathering, the Beech Bottom deposit, and probably Wellsburg deposit are younger than Illinoian.

In contrast, the Follansbee alluvium is less-weathered than the Beech Bottom alluvium. The soil developed in the 0.9 m (36 inch) thick silt mantle has a 0.44 m (17.3 inch) thick Bt horizon with weak subangular blocky structure. Compared to Beech Bottom's soil, the Bt is half as thick and the soil structure is much weaker. The underlying gravels, including Canadian Shield erratics, limestones, and sandstones, were all relatively unweathered. Follansbee's gravels are weathered to a similar degree as those at the same stratigraphic position (under a thin silt mantle) under S5 at the East End and Newell 1 sites. The S5 deposits at East End and Newell have been correlated to the early Wisconsinan Titusville Till (White, 1982). Hence, the Follansbee alluvium appears to be younger than the Beech Bottom alluvium and is here considered the same age as S5 deposits, early Wisconsinan.

The alluvium at Weirton, Beech Bottom, and probably Wellsburg post-date the Illinoian, as used by Lessig (1959a; 1959b) and Jacobson (1985), and pre-date the early Wisconsinan (Fullerton, 1986) based on a greater than 40,000 yr. B.P. date, bedrock and surface elevations lower than mapped Illinoian, bedrock elevations higher than those underlying Titusville outwash, correlated as early

Wisconsinan by White, (1982), and weathering of soils and gravels. Therefore, the S7 deposits are probably Sangamonian based on morphologic relationships with landforms whose ages are inferred by others.

DEPOSITS

The eight fluvial surfaces along the Upper Ohio River Valley are underlain by a combination of five different facies (Simard, 1988). The different facies were observed at numerous exposures in the field and verified with laboratory analysis. Each facies is summarized in Table III and illustrated in figures 7 and 9. Of the five facies, only the coarse-grained Ohio River alluvium and eolian sand meet the requirements of a construction aggregate for concrete.

The coarsest, most dominant facies, coarse-grained Ohio River alluvium, consists of poorly sorted, well-rounded gravel, sand, and minor silt and clay. Gravels in this unit are mainly local Pennsylvanian and Permian sandstones with some shales, siltstones, vein quartz, quartzites, cherts and about 3 to 7% Canadian Shield erratics. This facies is an important source of construction material aggregate because the clean, well-rounded, hard gravels, and the low amount of silt and clay make a strong concrete (American Society for Testing Materials, 1978). The coarse-grained alluvial facies dominates at the sample sites of East End, Newell 1, Newell 2, Power, Dilles Bottom, and New Martinsville. Figure 11,

TABLE III: SUMMARY OF FACIES OF THE OHIO RIVER VALLEY FILL

FACIES NAME	MIALL (1981) NOMENCLATURE	ORIGIN	SEDIMENT TYPE	SEDIMENTARY STRUCTURES	LANDFORM OCCURRENCE	COMMENTS
coarse-grained Ohio River alluvium	Gm, Gt, Gp	outwash	rounded to well rounded gravels stratified with sand, minor silt, and clay	horizontal, trough, and planar crossbeds	terraces and floodplains	gravels include crystallines, quartzite, chert, vein quartz
tributary alluvium	Gm, Gt, Gp	tributary stream	subrounded gravel stratified with more sand, silt and clay than coarse-grained Ohio River alluvium	trough and planar crossbeds	terraces and floodplains	local lenses within coarse-grained Ohio River alluvium
colluvium	Gms	gravity deposits	matrix supported angular gravels of sandstone, shale and siltstones	none	terraces and floodplains	interfingers with alluvium at valley walls
fine-grained Ohio River alluvium	Fl	overbank or waning flood deposits	sand, silt, and clay	none seen	terraces and floodplains	occasional lenses of sand and gravel
eolian sand	Spe, She	eolian deposits	sand	planar crossbeds	terraces	hummocky, dune-like topography
eolian silt	?	eolian deposits	silt	none	terraces	none

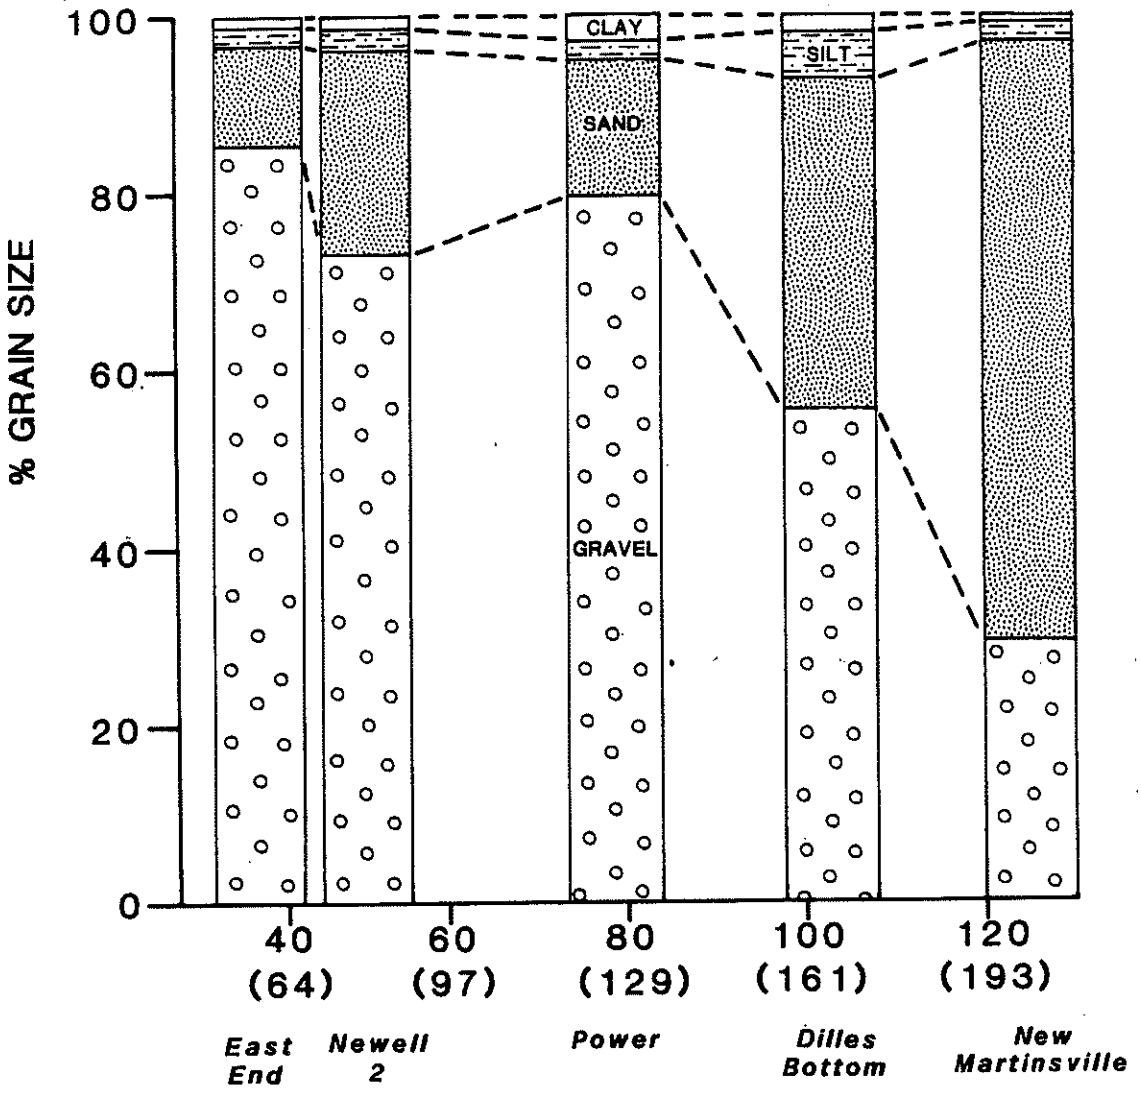

Figure 11. Histograms showing downstream changes in grain size of coarse-grained Ohio River alluvium. Sample sites shown on figures 1 and 5.

shows that the percentage of gravel occurring at these localities decreases from 86% at East End to 30% at New Martinsville. Correspondingly, mean grain size decreases downstream (fig. 12). The downstream decrease in grain size is a function of larger, heavier grains being deposited near their source and a reduction of clast size through abrasion.

A plot of pebble counts for selected samples at Newell 2, Dilles Bottom, and New Martinsville (fig. 13) shows a downstream increase from 5 to 9% in Canadian Shield erratics and quartzites. These lithologies do not crop out in the Ohio River basin; hence, they were introduced to the Ohio River Basin as outwash from the Laurentide Ice Sheet. Vein quartz does not crop out in the field area but can also be reworked from conglomerates that crop out in the basin and, therefore, is not exclusively an indicator of an outwash origin. The dramatic increase in chert in both late Wisconsinan S4 (New Martinsville) and early Wisconsinan S5 (Dilles Bottom) deposits indicates that there is a downstream increase in chert for each different-aged outwash. Local limestone units along the Ohio River Valley contain small amounts of nodular chert which may have been added to the outwash by local tributaries. Arkle and others (1967) speculate that the downstream increase in chert is due to its tendency to fracture and pit, thereby increasing in concentration in the smaller gravel and sand sizes. The total volume of chert may be due to a downstream increase in

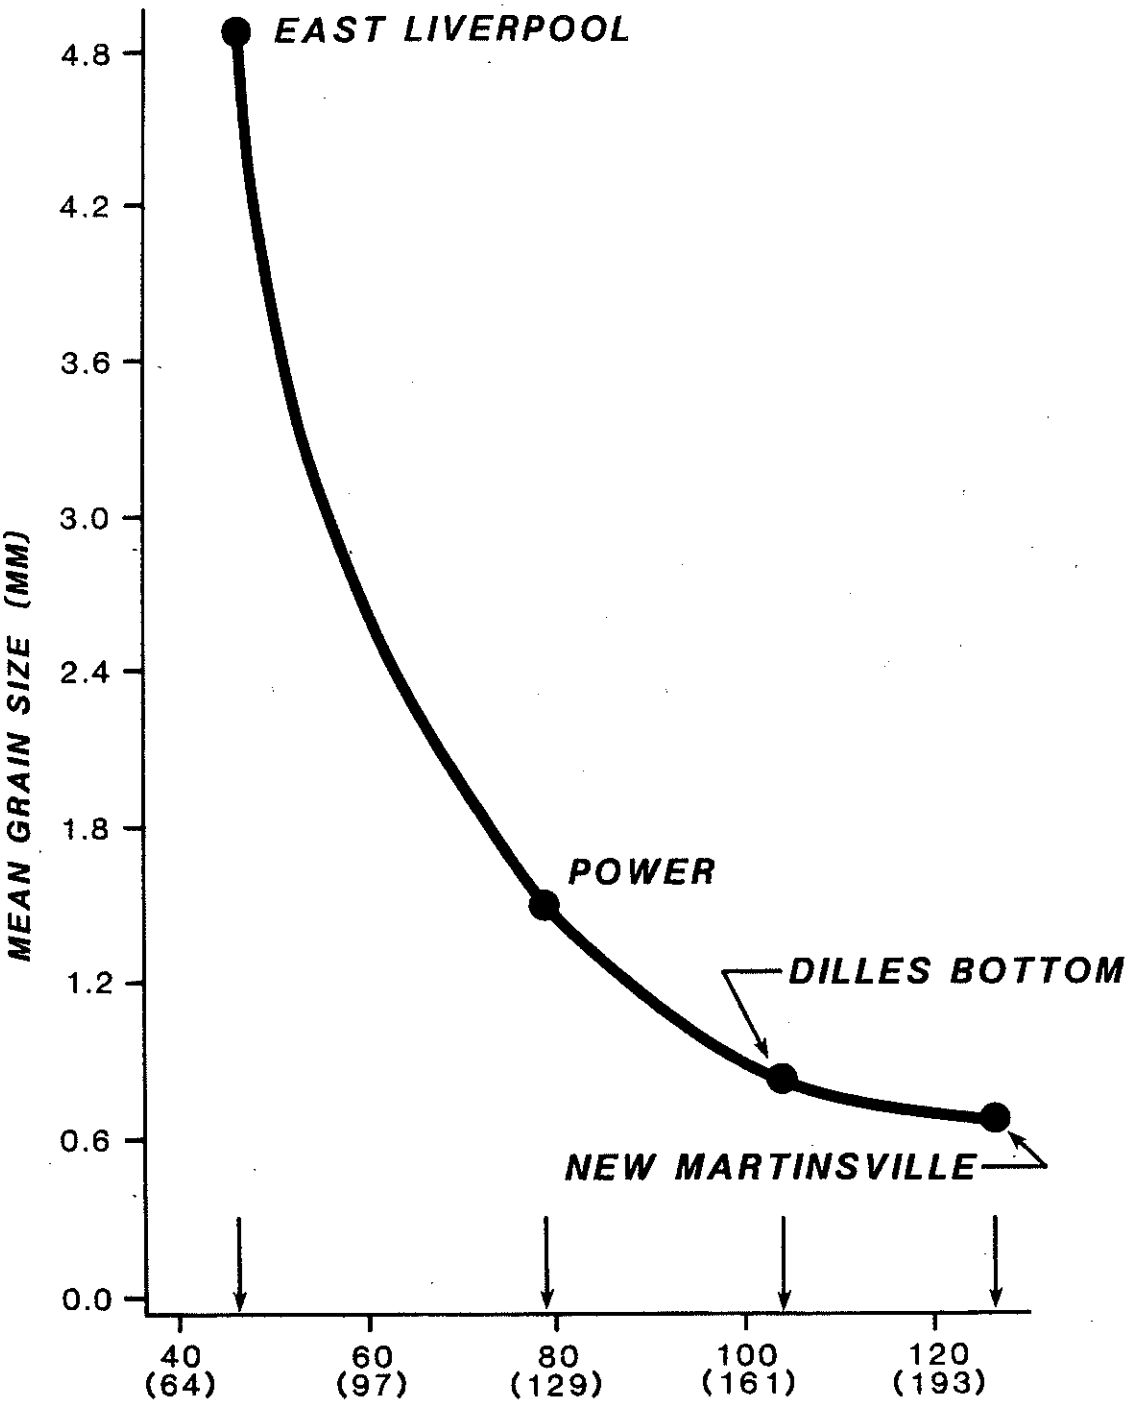

Figure 12. Graph showing downstream decrease in mean grain size of coarse-grained Ohio River alluvium. Sample sites shown on figures 1 and 5.

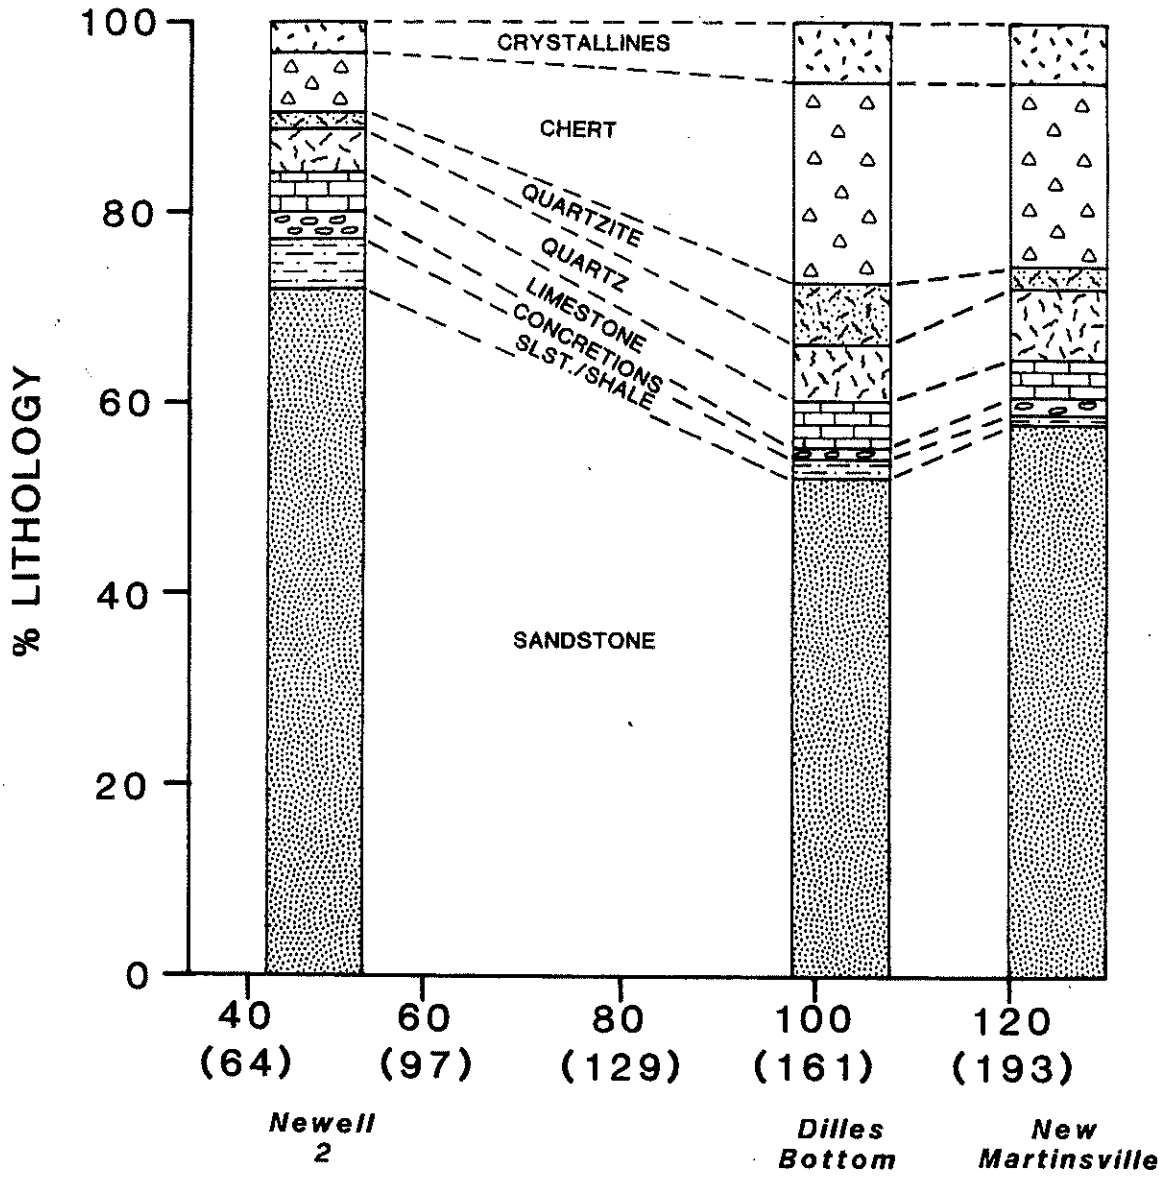

Figure 13. Histograms of gravel (12.7 to 6.35 and 4.00 to 2.00 mm) lithology in coarse-grained Ohio River alluvium versus distance downstream. Sample sites shown on figures 1 and 5. Sample data are in Appendix V.

concentration by reworking from outwash and local sources. Chert is detrimental to concrete because it expands when reacting with alkalies in cement, thereby causing cracks and weakening of concrete (American Society for Testing Materials, 1978).

Coarse-grained Ohio River alluvium also includes a high percentage of well-rounded, spherical pebbles, as documented at sample sites Newell 2, Dilles Bottom, and New Martinsville (figs. 14 and 15). The distinct downstream increase in roundness and the gradual increase in sphericity downstream occurs from abrasion with greater distance traveled.

The stratigraphy of the coarse-grained Ohio River alluvium consists of lenses of planar and trough cross-bedded sand and gravel, planar and trough cross-bedded sands, and minor thin silt beds. Grain size changes abruptly both vertically and horizontally due to the lenticular nature of the beds. Based on the coarse grain size and coarse sedimentary structures, the environment of deposition of the coarse-grained Ohio River alluvium is interpreted as channel fill and bars of an aggrading braided stream system (Miall, 1981).

The second facies is composed of finer-grained tributary alluvium which forms local lenses within the coarser-grained Ohio River alluvium. Gravels in the tributary alluvium are predominantly flat, subrounded sandstones with some shale and

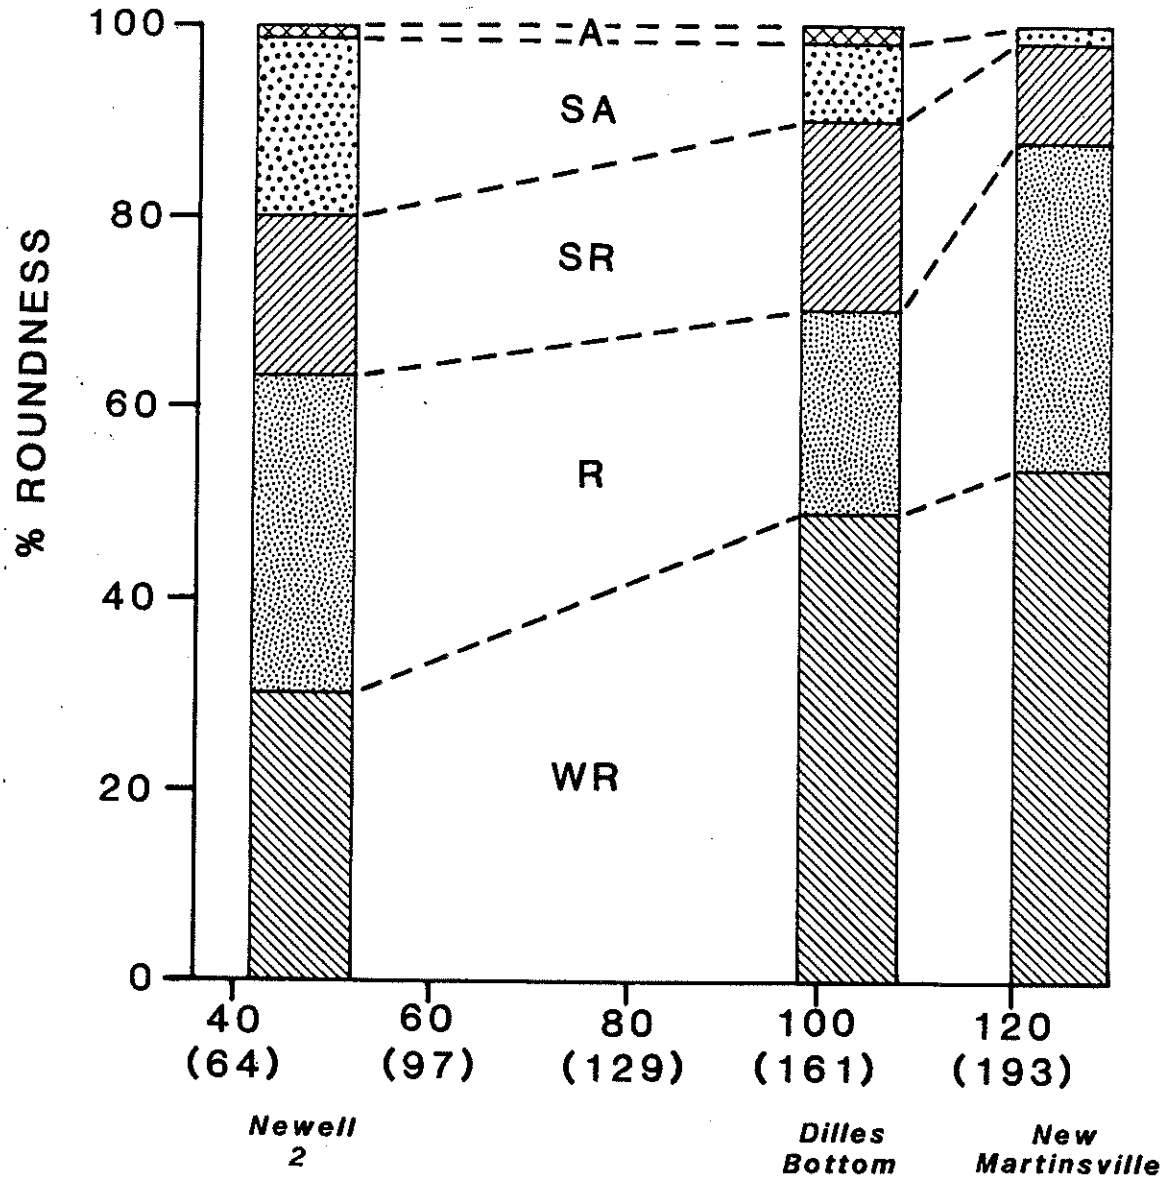

Figure 14. Histograms of gravel (6.35 mm) roundness of coarse-grained Ohio River alluvium versus distance downstream. WR = well rounded, R = rounded, SR = subrounded, SA = subangular, A = angular. Sample site locations shown on figures 1 and 5. Sample data are in Appendix V.

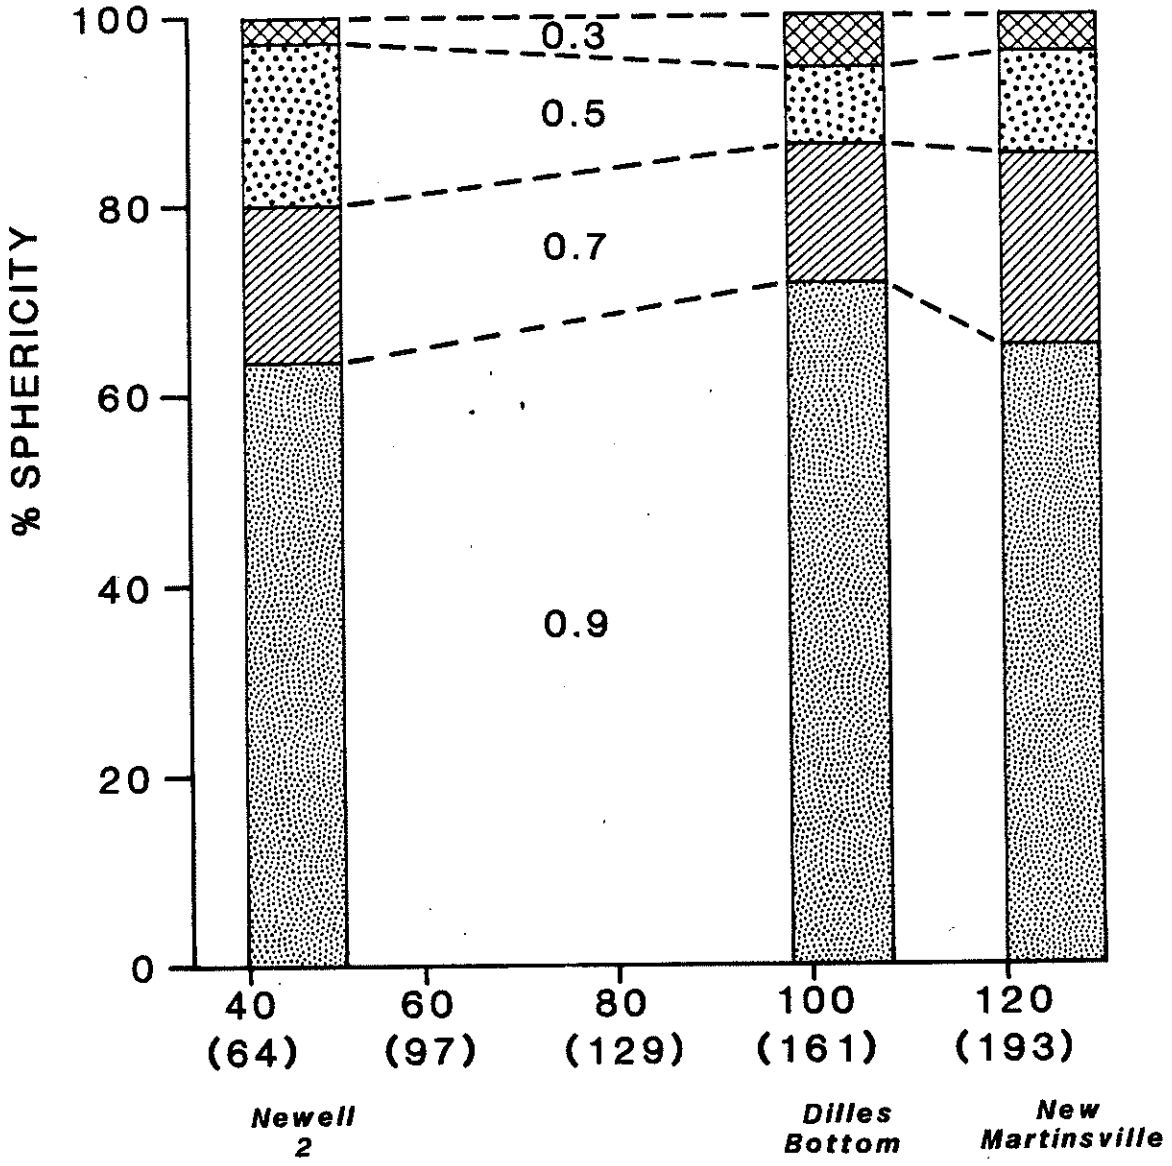

Figure 15. Histograms of gravel (6.35 mm) sphericity in coarse-grained Ohio River alluvium versus distance downstream. 0.9 = most spherical, 0.3 = least spherical. Sample site locations are shown on figures 1 and 5. Sample data are in Appendix V.

more sand and silt than coarse-grained Ohio River alluvium. This facies includes soft, weakly cemented, local sandstone and shale, and too much silt and clay to be an economic resource of construction aggregate. The Chester site contained some tributary alluvium facies, whereas the Follansbee sand and gravel site was primarily tributary alluvium. Figure 16 illustrates the greater percentage of sand, silt, and clay of the tributary facies compared to coarse-grained Ohio River alluvium. A sample at Follansbee contains 99.3% gravels of local origin compared to an average of 88.6% in two coarse-grained Ohio River alluvium samples at nearby Beech Bottom (fig. 17). The extra-basinal quartzite and Canadian Shield erratics in the tributary alluvium are from contemporaneous deposition with coarse-grained Ohio River alluvium or incorporation from higher terrace deposits. Figure 18 illustrates the predominance of subrounded gravels in the tributary samples compared to the greater number of well-rounded gravels in the coarse-grained Ohio River alluvium samples. A graph of gravel sphericity (fig. 19) shows that both facies have about the same amount of the most spherical gravels (0.9) but the tributary alluvium has more of the less spherical gravels (0.5 and 0.3).

The Chester and Follansbee sites have lenses of silt, planar and trough cross-bedded sands, and planar cross-bedded sand and gravel similar to bed forms in the coarse-grained

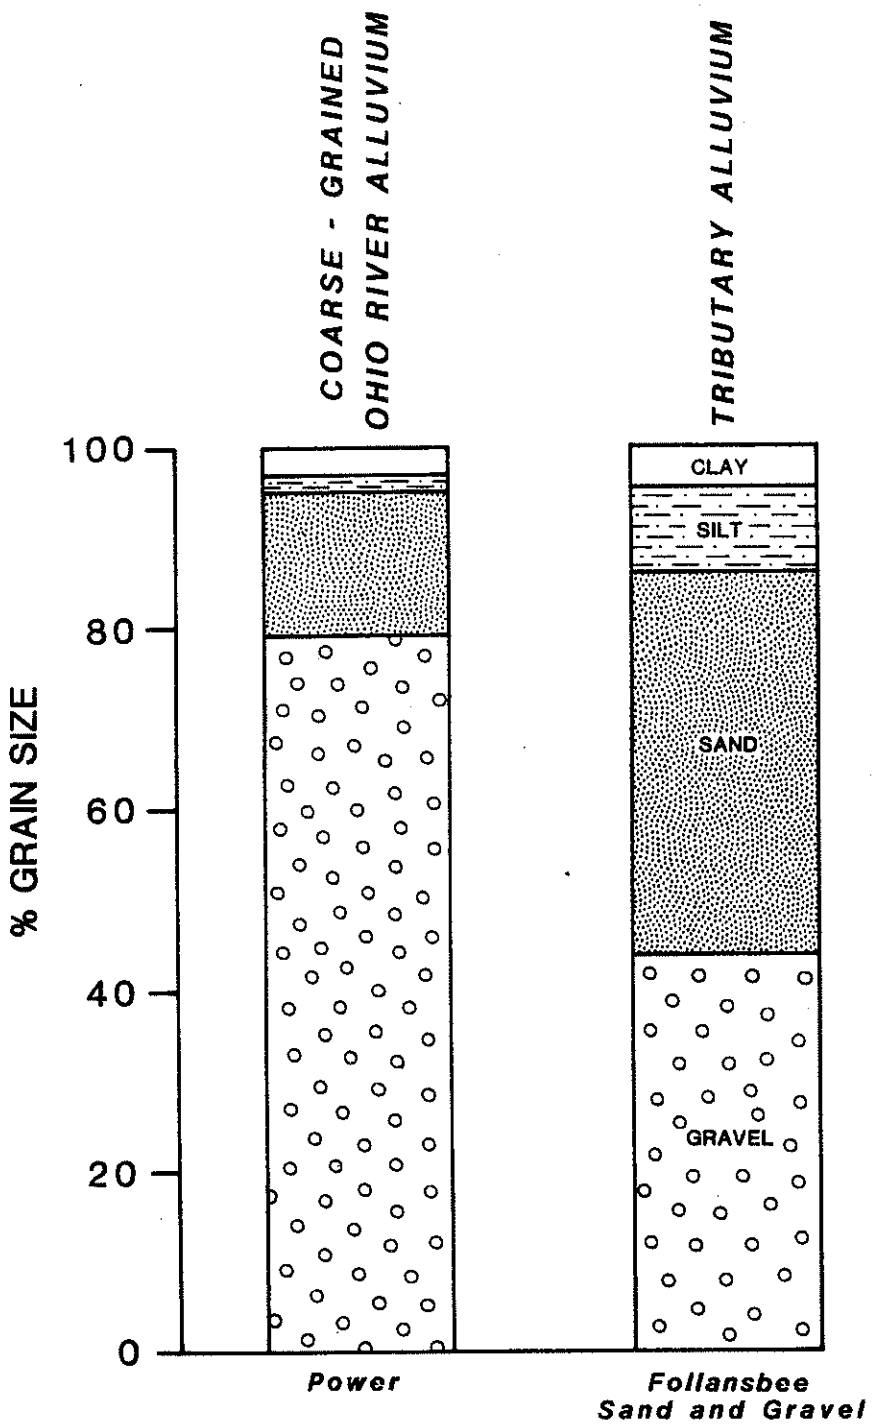

Figure 16. Histograms of grain size of coarse-grained Ohio River alluvium versus tributary alluvium. Grain size analysis if for each site. Site locations are shown on figures 1 and 5.

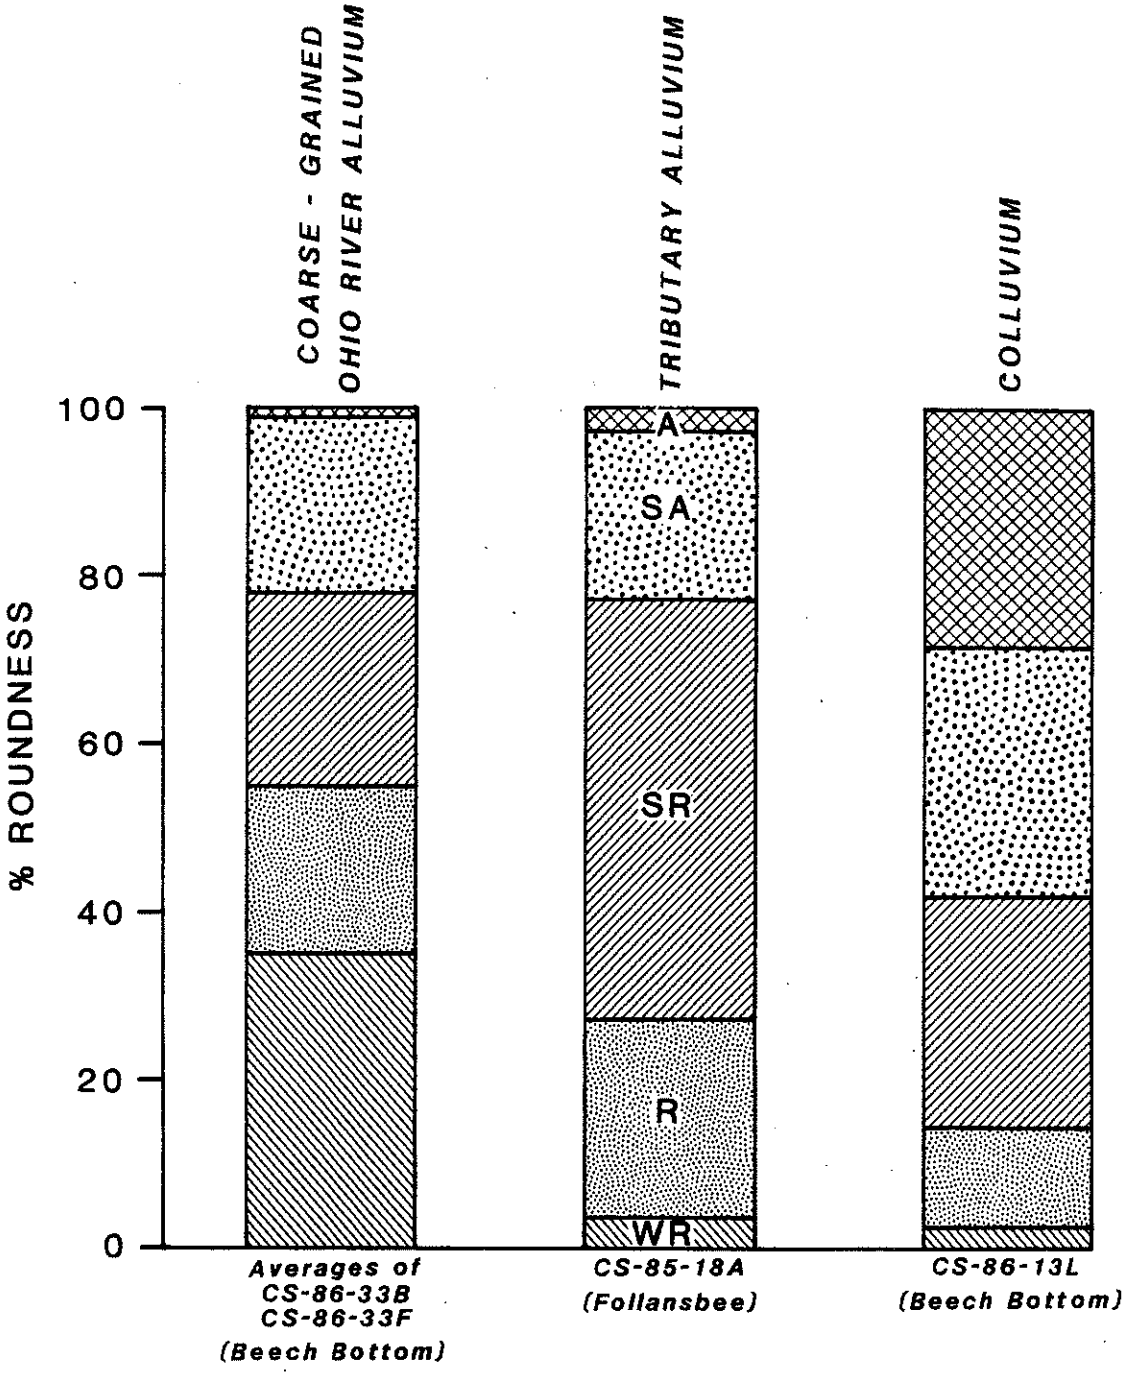

Figure 18. Histograms comparing gravel (6.35 mm) roundness of coarse-grained Ohio River alluvium, tributary alluvium, and colluvium. WR = well rounded, R = rounded, SR = subrounded, SA = subangular, and A = angular. Sample site locations are shown on figures 1 and 5.

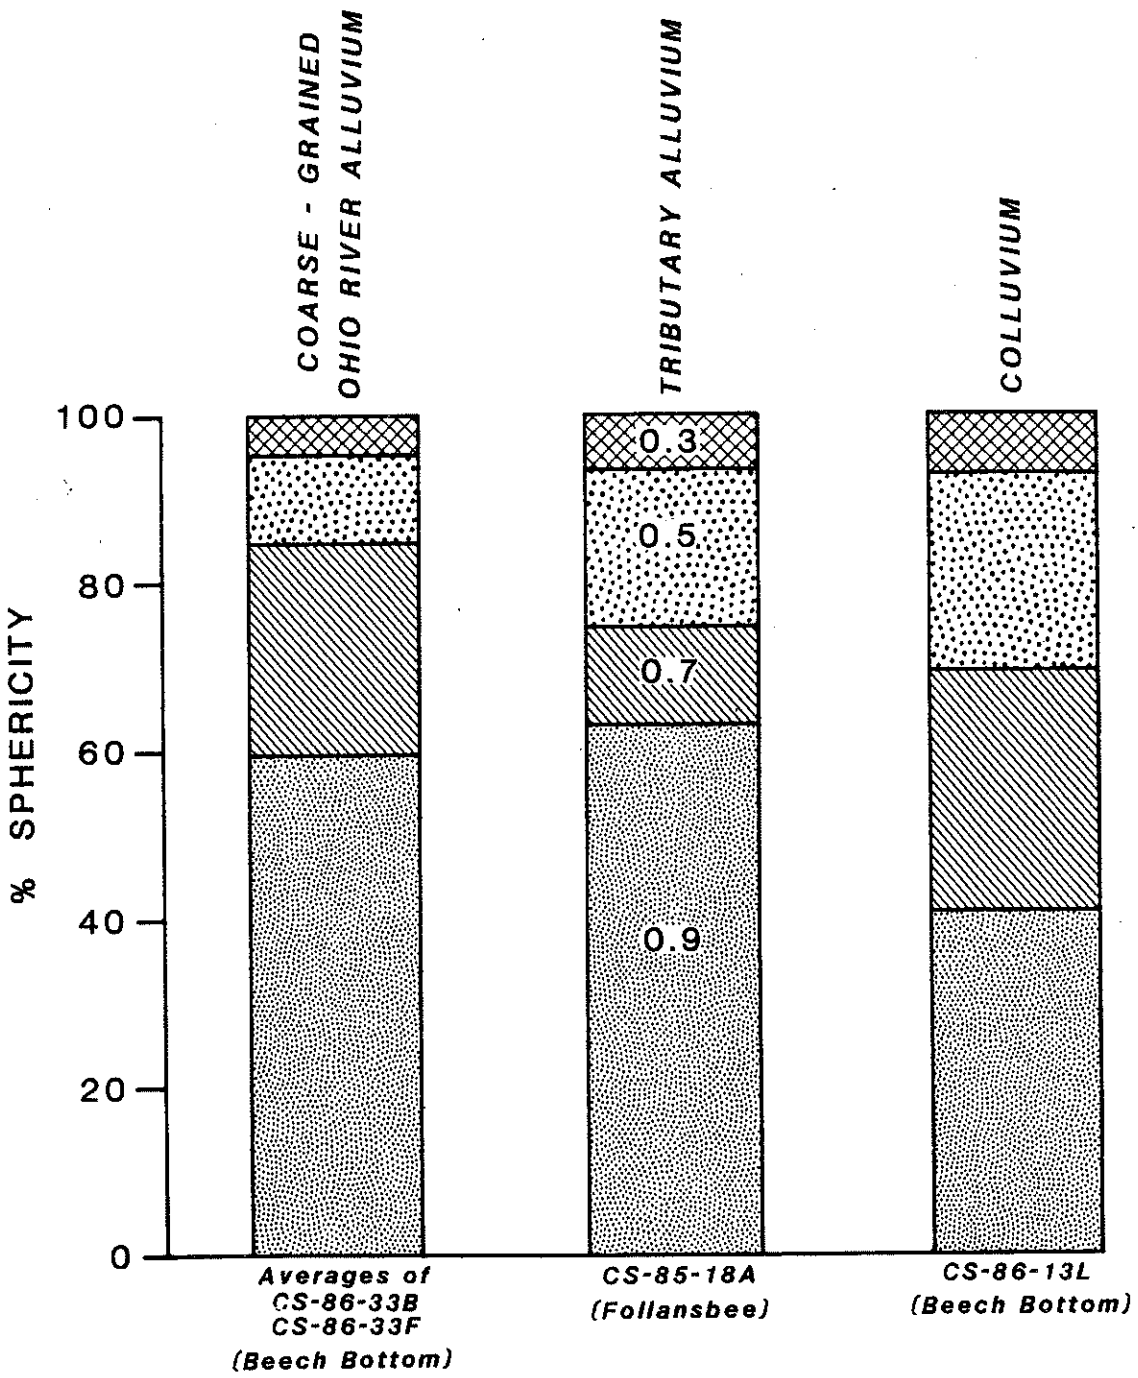

Figure 19. Histograms comparing gravel (6.35 mm) sphericity of coarse-grained Ohio River alluvium, tributary alluvium, and colluvium. 0.9 = most spherical, 0.3 = least spherical. Sample site locations are shown on figures 1 and 5.

Ohio River alluvium but on a smaller scale. Figure 20 depicts the sample site, grain-size distribution, and soil horizons at the Follansbee site. The relatively coarse grain size and varying sedimentary structures are interpreted as channel fill and bars of an aggrading tributary keeping up with the rising base level of the aggrading Ohio River channel.

The third facies consists of colluvial deposits interfingering with the alluvial fill at the valley walls. This facies is characterized by angular sandstone gravels with more shale and siltstone gravels than any other facies. Colluvium has too much silt, clay, and soft (poorly cemented), angular local sandstone and shale gravels for use as a concrete aggregate. In the histograms of figures 17, 18, and 19, sediment dominated by colluvium at Beech Bottom is compared to the coarse-grained Ohio River alluvium at the same site and tributary alluvium at Follansbee. Figure 17 illustrates the greater amounts of shale/siltstone and concretions in the colluvium dominated facies as compared to both alluvial facies. The 3% Canadian Shield erratics are from the interbedding of coarse-grained Ohio River alluvium with colluvium. Figure 18 shows the much greater amount of angular and subangular gravels in the colluvium dominated gravels compared to tributary and coarse-grained Ohio River alluvium. A decrease in sphericity of the colluvium dominated gravels as compared to the alluvial gravels is

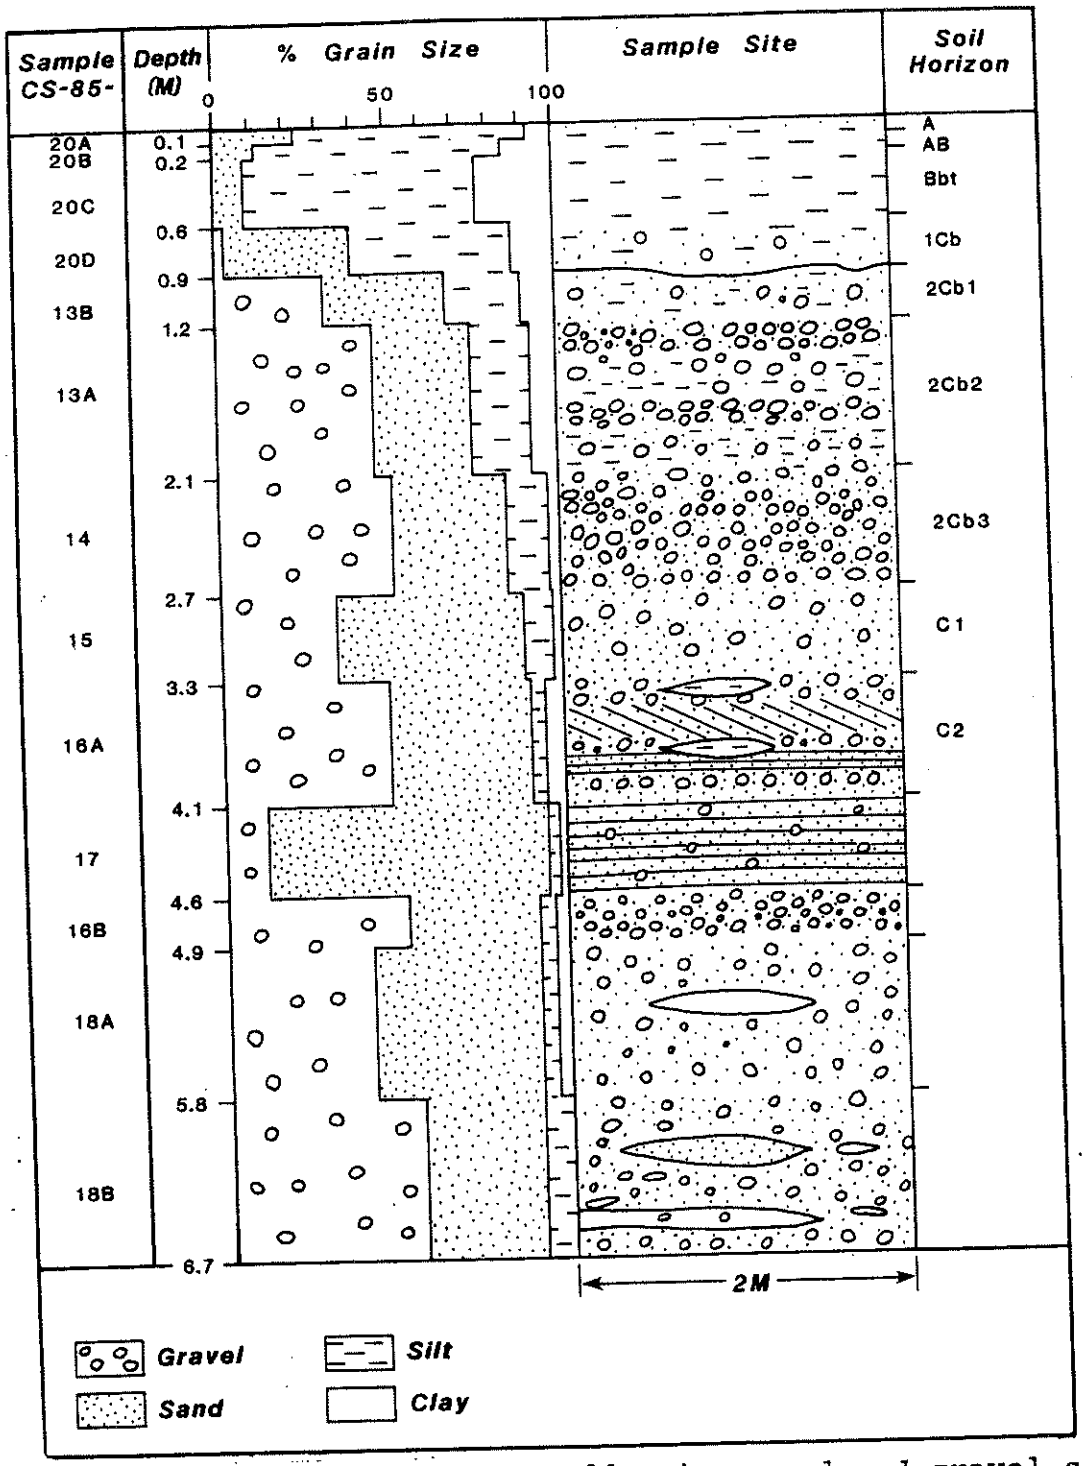

Figure 20. Soil profile of Follansbee sand and gravel site. Grain-size distribution (left) is compared to sampled site (center), and soil horizons (right). Sample site location is shown on figures 1 and 5. Fine-grained Ohio River alluvium occurs from 0 to 0.9 m. Tributary alluvium occurs from 0.9 to 6.7 m depth.

illustrated in figure 19. Colluvium can also be identified in the field by the matrix-supported gravel and very weak bedding.

The coarse deposits of S0 through S3 and parts of S4 through S7 are capped by the fine-grained Ohio River alluvial facies of overbank silt, sand, and clay. The facies is a fining-upward sequence characterized by a thin basal, transitional, gravelly, sandy silt, fining upward to a silt unit as seen at the exposure sites of East End, Newell 1, and Follansbee sand and gravel. The Follansbee sand and gravel site, the most complete profile, is illustrated in figure 20. The overbank alluvium at this site may have been deposited by a tributary (the underlying sand and gravel is predominantly tributary alluvium) instead of the Ohio River, but it is of overbank origin. The transitional zone at a depth of 0.6 to 0.9 m (24 to 36 inches) includes minor gravel, and almost equal amounts of sand and silt, as shown in the grain-size percentage profile (fig. 20). The average particle size of the profile is dominated by silt from a depth of 0.9 m to the surface (Table IV). No sedimentary structures were seen in the silt, probably because of pedoturbation and bioturbation. However, in U. S. D. A. Soil Conservation Service descriptions of the soils developed on the floodplains, the sand, silt, and clay is sometimes stratified at depth (see Table II for soil series). Overbank alluvium is too fine for construction aggregate and is considered an "overburden" that

must be removed prior to quarrying the underlying sand and gravel.

Discontinuous mantles of sand and silt on terraces S3 through S7 represent a possible eolian facies (Ellyson and others 1970, 1974; Kunkle and others, 1960; Lessig and others, 1977; Rubel and others, 1981). The composition of the mantle is mostly sand from Arroyo (river km 81, mile 50) to Follansbee (km 113, mile 70), and mostly silt at Moundsville (km 164, mile 102), Dilles Bottom, Ohio (km 166, mile 103), Round Bottom (km 171, mile 106), and the Steelton area of New Martinsville (km 201, mile 125). Sand and silt mantle the terrace surfaces in Wood County. Silt also mantles low-lying bedrock surfaces of the valley walls.

Table IV compares the Beech Bottom silt mantle (of possible eolian origin), the Follansbee (sand and gravel site) overbank silt cap, and North American and European proglacial loess (Ashley, 1985). The Beech Bottom silt deposit has a three times greater thickness, more silt and clay, and correspondingly, a finer mean grain size than the Follansbee silt deposit. Sorting for both deposits is the same. The average grain size of both deposits falls within the grain-size range of proglacial loess, but both have a finer mean grain size than loess. Pedogenic processes, especially at the older, more weathered Beech Bottom site, may have reduced some of the particles to a smaller size, reducing the mean grain size in the process. However, the

TABLE IV: COMPARISON OF OVERBANK ALLUVIUM AND EOLIAN SILT GRAIN SIZE ANALYSIS

SITE NAME	UNIT THICKNESS m (ft)	TOTAL % SILT				% AVERAGE GRAIN SIZE/PROFILE				MEAN (phi)	SORTING (phi)
		coarse 5 phi	medium 6 phi	fine 7 phi	coarse to fine 5 to 7 phi	gravel	sand	silt	clay		
FOLLANSBEE	0.9 (3)	28	17	9	54	0.4	22	64	14	6.6	2.3
BEECH BOTTOM	3.4 (11)	16	22	7	55	-	6	70	24	7.8	2.3

* from North America and Europe (Ashley, 1985)

original grain size cannot be determined because the whole profile is extensively weathered. No sedimentary structures were found in the silt cap at Beech Bottom possibly because of extensive pedoturbation and bioturbation. The lack of the basal, transitional, gravelly silt, the slightly finer silt, and the approximately three times greater thickness of silt at Beech Bottom compared to Follansbee may be indicative of an eolian rather than overbank deposition, but, this interpretation cannot be supported by grain size analysis when compared to proglacial loess reported by Ashley (1985).

Measured sections of S5 at Arroyo and Follansbee sand pit show 3.7 m (12 ft) and greater than 2.6 m (8.5 ft), respectively, of medium-to-fine sand with planar cross-beds of thinly laminated graded bedding. The sand can be used as a fine aggregate in concrete. The Follansbee deposit appears on a 7.5-minute topographic map and in the field as an elongate tongue shape. The deposits at Arroyo appear on a 1956 aerial photograph as irregular mounds. Almost all the sand deposits were removed during the process of sand and gravel quarrying at the Arroyo sample site prior to this study. The dimensions of the Follansbee sand deposit, as measured from a 7.5 minute topographic map, is a maximum of 90 m (300 ft) wide and 210 m (700 ft) long. Field observation shows the deposit rises about 3 m (10 ft) above the surrounding terrace. The dimensions of the sand deposits at Arroyo were approximately 50 m by 50 m (160 by

160 ft), as measured from the aerial photograph. Mechanical analysis revealed 32 to 54% in the 3 phi (fine sand) size in five of the eight samples at Arroyo and 41 to 57% in the 3 phi sand size in the eight samples at Follansbee. Grain size of the whole profile was 78% sand at Arroyo and 80% sand at Follansbee. Ashley (1985) characterized worldwide proglacial eolian sand as well-sorted sand in the medium-to-fine size with planar crossbeds and graded bedding. Because of dune-like geomorphic expression of the surfaces, the high percentage of well-sorted fine sand, graded bedding, planar crossbeds, and the lack of trough crossbeds in these exposures, these sand facies in the study area are interpreted as eolian.

Figure 9 shows that each of the eight surfaces is underlain by a composite of coarse-grained Ohio River alluvium, tributary alluvium, and colluvium deposits (against the valley walls). Sand and gravel deposits decrease in thickness toward the river, according to available core and water well logs (Table II). Maximum thickness of sand and gravel decreases from 45 m (147.6 ft) under S6 to 15.2 m (49.7 ft) under S0 and S1. Terraces S4, S5, and S6 are overlain by 0 to 6 m (0 to 20 ft) of fine-grained Ohio River alluvium locally capped by 1.5 to 4.6 m (2.5 to 15 ft) of possible eolian sand and silt deposits. Terrace S3 and floodplain surfaces S2, S1, and S0 are covered by 1.1 to 11.3 m (3.6 to 37 ft) of fine-grained Ohio River alluvium.

RADIOCARBON DATES

Radiocarbon dates from organic material within the deposits are an important part of interpreting the geologic history of the surfaces. The radiocarbon dates, as plotted on the surfaces defined in this study, either confirm or refute previous correlations based on soil development and tracing surfaces downstream from early-and late-Wisconsinan tills.

The author knows of six radiocarbon dates available in the study area; three for S2, two for S4 and one for S7. The following descriptions of the radiocarbon dates are given in the order of lowest to highest surface and proceeding downstream for each surface. Table V is a summary of information for each date and figure 8 shows their location and depth below each surface.

A tree branch in an old colluvial failure surface was dated as a 9750 $\pm$ 200 yr. B.P., (lab number not given; Philbrick, 1961) in the deposits underlying S2 at Pike Island Lock and Dam (river km 136, mile 84.3). The approximately 27.4 m (90 ft) thick deposit includes overbank fines (fine-grained Ohio River alluvium) overlying sand and gravel (coarse-grained Ohio River alluvium), both interfingering with and overlain by colluvium at the valley walls (Gray and others, 1979). The colluvial slide plane was overlapped by sand and gravel (Philbrick, 1961). Figure 8

TABLE V: RADIOCARBON DATES

DATE (yr. B.P.)	LAB NUMBER	SITE NAME	SURFACE	DESCRIPTION	REFERENCES
9750 ± 200	Not given in reference	Pike Island Lock and Dam	S2	Tree branch in colluvial slide-plane interbedded with sand and gravel. Branch found about 5.5 m (18 ft) below surface of a 21 m (70 ft) alluvial deposit (silt and clay overlying sand and gravel). Colluvium interbeds and overlies alluvium.	Philbrick (1961); Gray and others (1979)
5000 ± 70	Beta-18553	Blennerhassett Island	S2	Elm log (genus Ulmus) found below 9 m (30 ft) of silty clay and 4 m (13 ft) of sand and gravel. The alluvial deposit was 17.5 m (57.3 ft) thick.	This study; W. Gillespie, personal communication (1986)
5120 ± 300	W-5884	Blennerhassett Island	S2	Elm log (genus Ulmus) found below 9 m (30 ft) of silty clay and 4 m (13 ft) of sand and gravel. The alluvial deposit was 17.5 m (57.3 ft) thick.	This study; W. Gillespie, personal communication (1986)
22,340 ± 960	I-9387	McMechen	S4	Wood fragment found below 3 m (10 ft) of colluvium and 2.4 to 3 m (8 to 10 ft) of alluvium in a 12.5 m (41 ft) thick alluvial deposit.	R. Gray, personal communication (1986); Gray and Gardner (1977)
13,510 ± 270	SI-5480	Boaz	S4	Mammoth bone at depth of 4.6 m (15 ft) under 1.8 m (6 ft) of silty sand and 2.7 m (9 ft) of sand and gravel in a 18.3 m (60 ft) thick alluvial deposit.	Fonner (1980; 1982)
> 40,000	Not given in reference	Weirton	S7	Organic material at base of colluvium overlying alluvium. Colluvium overlies about 10 m (30 ft) of silt and clay and about 15 m (50 ft) of sand and gravel.	D'Appolonia and others (1967); Gray and others (1979)

shows the tree branch was approximately 5.5 m (18 ft) below the surface of the approximately 21 m (70 ft) thick alluvial deposit underlying S2 (Gray and others, 1979). The age of the tree branch, 9750 ± 200 yr. B.P. post-dates the Kent advance which ended approximately 16,000 yr. B.P. (Fullerton, 1986). The post-Wisconsinan date (Table I) indicates that coarse-grained Ohio River alluvium was reworked during the Holocene. The post-Kent age of this deposit conflicts with the late Wisconsinan Kent correlations of the Chili series soils in Columbiana County, Ohio (Lessig, 1961b). Therefore, either the age correlations of Lessig cannot be extended downstream or the Columbiana County Chili series soils are not exclusively confined to late Wisconsinan Kent outwash.

Two logs, dated as 5000 ± 70 yr. B.P. (Beta-18553) and 5120 ± 300 yr. B.P. (W-5885), were found below S2 at Blennerhassett Island (fig. 8) during the drilling of I. E. Dupont De Nemours Company water well 436. The logs, identified as the genus Ulmus (W. Gillespie, personal communication, 1986), were located in a 17.5 m (57.3 ft) thick alluvial deposit under 9 m (30 ft) of silty clay (fine-grained Ohio River alluvium) and 4 m (13 ft) of sand and gravel (coarse-grained Ohio River alluvium). The presence of coarse-grained Ohio River alluvium (outwash) imbedded in the logs and the absence of silt and clay under the outwash gravels verifies that the wood did not fall from the silty clay to that level during the cable tool drilling. The

Blennerhassett Island site is located 169 km (105 miles) downstream of the Pike Island Lock and Dam site, and 29 km (18 miles) downstream from the mouth of the Muskingum River (fig. 8). The Holocene ages of both of these S2 sites indicates continued reworking and redeposition of coarse-grained Ohio River alluvium deposits after glacial retreat. The post-Kent age of these deposits also conflicts with the late Wisconsinan Kent correlations of the Chili series soils in Columbiana County, Ohio (Lessig, 1961b; Lessig and others 1968), as explained in the discussion of for the Pike Island Lock and Dam radiocarbon date.

In McMechen (river km 155, mile 96.5), a wood fragment underlying S4 was dated as 22,340 $\pm$ 960 yr. B.P. (I-9387) (Gray and Gardner, 1977). The core log shows that the wood was at a 5.4 m to 6 m (18 to 20 ft) depth, below 3 m (10 ft) of colluvium and 2.4 to 3 m (8 to 10 ft) of alluvium. The alluvial deposit was 12.5 m (41 ft) thick (R. Gray, personal communication, 1986). The alluvium is described as clayey silt with a trace of rock fragments, chiefly flat to subrounded sandstones and shales. Because of the large amount of silt and clay, the paucity of gravels, and the flat, subrounded shape of the gravels present, the deposit is interpreted as tributary alluvium. No other core logs are available for S4 in the immediate area. However, three nearby water well logs on S3 (Appendix II) describe coarse-grained Ohio River alluvium under 4 m (13 ft) of "surface

soil and clay". Assuming the tributary alluvium is a lense within coarse-grained Ohio River alluvium, and the wood was not reworked from an older deposit, the S4 alluvium was deposited at the time of the Kent advance (Table I).

Mammoth bone fragments, dated as 13,510 ± 270 yr. B.P. (SI-5480) (Fonner, 1982) were found in a gravel pit on S4 at Boaz, 128 km (79.5 miles) downstream from McMechen (fig. 8). The bones were found 4.6 m (15 ft) below the original surface, under 1.8 m (6 ft) of silty, fine-sand and 2.7 m (9 ft) of sand and gravel (Fonner, 1982). The whole deposit was reported by the gravel pit owners to be 18.3 m (60 ft) deep. Fonner described the top 1.8 m (6 ft) as "fine, sandy-silt topsoil" and "silty, fine-sand loess (?)" and the underlying sand and gravel as including chert and granite clasts. The relatively young date for this high level surface could be attributed to influx of post-Kent advance (Table I) sediment from the Muskingum River, located 6.4 km (4 miles) upstream. Underlying this young, coarse-grained Ohio River alluvium may be older Ohio River alluvium from upstream on the Ohio. Therefore, the date of 13,510 ± 270 yr. B.P. may not represent the age of the S4 surface north of the Muskingum River's mouth, but is the maximum age for the surface at this location.

The late Wisconsinan dates at McMechen and Boaz (obtained in 1976 and 1981, respectively) conflict with the early Wisconsinan correlations of S4 and its Negley series

soil in Columbiana County, Ohio (Lessig, 1961b). Either Lessig's correlations of the Negley series soils in Columbiana County cannot be extended downstream, or the Negley series is not exclusively an indicator of early Wisconsinan soils.

The oldest radiocarbon-dated material was found in sediment underlying the S7 surface in the abandoned channel at Weirton. Organic material dated as greater than 40,000 yr. B.P. (no lab number given) was found at the base of colluvium overlying an alluvial deposit. The colluvium covers approximately 10 m (30 ft) of silt and clay (fine-grained Ohio River alluvium) that overlies up to 15 m (50 ft) of sand and gravel (coarse-grained Ohio River alluvium) (D'Appolonia and others, 1967; Gray and others, 1979). The radiocarbon date shows that the overbank sediment is at least older than late Wisconsinan Kent advance (beginning 23,000 yr. B.P.) and could be correlative to the early Wisconsinan Titusville advance, which Fullerton (1986) states begins 79,000 and ends 65,000 yr. B.P., or older. Organic material from an older source could have been incorporated into younger colluvium because the material was found at the base of the colluvium and not in the alluvium itself. If so, the age of the colluvium may not be truly represented, nor is the age of the underlying alluvial sediment truly limited. I feel the age of the surface is between early Wisconsinan and Illinoian, however, because the bedrock and surface

elevations are lower than that of mapped Illinoian terraces, and the bedrock elevations are higher than those underlying Titusville outwash, which correlated as early Wisconsinan by White (1982), and intermediate weathering of soils and gravels (see S7 in the Landforms section).

Two samples of mammoth bone fragments from a sand and gravel pit at Follansbee were submitted to the University of Michigan Museum of Anthropology for radiocarbon dating (Weimer, 1959). The samples (numbered M-513 and M-514) did not produce any dates because of inadequate levels of collagen (D. Kennedy, personal communication, 1986). The samples were apparently lost or destroyed when that radiocarbon lab ceased operations.

CHAPTER 5

GEOLOGIC HISTORY

The geologic history of the lower terraces and floodplains of the upper Ohio River Valley was determined from morphostratigraphy, tracing the surfaces upstream to early-and late-Wisconsinan tills, radiocarbon dates, weathering of the deposits and surfaces, and laboratory analysis of the deposits. However, the interpretation is limited by resolution of the landformtributarys (based mainly on 7.5-minute quadrangle maps with 20 foot contours and some 10 foot supplemental contours).

In general, the present course of the Ohio River was established before the Illinoian glaciation, as mentioned in the Previous Works section. Following the Illinoian, the river eroded downward forming the bedrock floor underlying S7. Sand and gravel alluvium aggraded to the level of S7 to a thickness of about 15 m (50 ft) in the abandoned channel at Weirton (D'Appolonia and others, 1967, fig. 1) and 7.3 m (24 ft) at Beech Bottom. Canadian Shield erratics in the S7 deposits suggest that the alluvium was either outwash or reworked outwash. Colluvium and local tributary alluvium was interbedded with the outwash. Weathering of the gravels, when compared to those mapped as Illinoian (Lessig, 1959a; 1959b; Jacobson, 1985) and early Wisconsinan (Titusville) age (Lessig, 1961b; White, 1982; and White and Totten, 1985),

indicates a post-Illinoian and pre-Wisconsinan age for the S7 deposits. The S7 bedrock and surface elevations are also lower than those mapped as Illinoian (Lessig, 1959a; 1959b; Jacobson, 1985) and higher than those correlated in this study to the early Wisconsinan. This age range is consistant with the greater than 40,000 yr. B.P. date (pre-late Wisconsinan--see Table I) at the abandoned channel at Weirton (D'Appolonia and others, 1967). Therefore, the S7 deposits may be Sangamonian-aged based on morphologic relationships with landforms whose ages are inferred by others.

Following the deposition of S7 alluvium, the broad, shallow, roughly U-shaped valley underlying the present Ohio River and S0 through S6 was scoured, possibly by an unusually severe or rare event. During the scouring, much of the alluvium and bedrock floor of S7 was eroded as the valley width doubled (compared to the width of the Weirton abandoned channel) and channel depth increased by about 21 to 27 m (70 to 90 ft) at Weirton (D'Appolonia and others, 1967, fig. 1). The remains of S7 were abandoned as a terrace. The Weirton channel was abandoned completely when the river was flowing at this new, lower level. Aggradation to the level of S6 probably occurred when meltwater of the Titusville advance, correlated as early Wisconsinan by White and Totten (1965) filled the Ohio River channel and its northern tributaries. At least 45 m (147.6 ft) of outwash from braided streams (as shown by the coarse cut and fill structures) was deposited

across from the mouth of Little Beaver Creek at Georgetown, Pennsylvania (fig. 1). White (1982) correlated the Georgetown deposit to the Titusville advance. The absence of S7 for 35 km (22 miles) downstream from the glaciated tributaries (fig. 8) suggests that S7 was buried there by the thick S6 deposits. The coarse deposits of S6 were later capped by fine-grained overbank alluvium as shown by core records at Georgetown (I. Maurer, personal communication, 1988). S5 formed approximately 6 m (20 ft) below S6 (fig. 8), probably from incision into the S6 alluvial fill, not bedrock. Incision probably occurred from reduced sediment load and a change in stream gradient after or during glacial retreat. In the process of incision, the river migrated vertically and laterally in the valley, reworking and redepositing floodplain material. The coarse lenses of cross-bedded sand and gravel seen at the large sand and gravel pit at Arroyo (18 km or 11 miles downstream from Georgetown) indicate that braided streams deposited S5 sediment at least at the top of West Virginia's northern panhandle (fig. 1). These coarse deposits were later capped by fine-grained overbank alluvium. The apparent absence of S6 from Weirton to just north of the Muskingum River's mouth (fig. 8), suggests that S6 was either eroded or buried by S5 deposits reworked from upstream at a lower gradient. The remaining deposits of S6, from upstream of Beaver River to Weirton and downstream from the Muskingum River, were

abandoned as a terrace as a result of incision. A segment of S5 occurs at the same elevation as S7. The absence of S7 downstream from Beech Bottom (fig. 5) suggests that it was buried during the deposition of S5. The slightly weathered gravels and poorly developed soil in the Follansbee alluvium overlying the elevated bedrock floor (correlative to the S7 bedrock floor) is interpreted as Titusville age. This age designation is based on similarity of weathering to the East End and Newell S5 deposits which were correlated to the Titusville advance (White, 1982). The younger S5 alluvium was probably deposited on the older, scoured S7 surface.

No radiocarbon dates are available for S5 and S6. The time interval between the beginning of Kent glaciation 23,000 yr. B.P. (Fullerton, 1986) and the alluvium deposited on S4 at McMechen (22,340 $\pm$ 960 yr. B.P.) seems too short for the deposition and erosion of S6 and S5, and subsequent deposition of S4 during the Kent advance. Therefore, S6 and S5 probably pre-date the late Wisconsinan Kent advance. They are probably early Wisconsinan rather than middle Wisconsinan, based on terrace correlations to the Titusville Till (White, 1982; White and Totten, 1985), which is designated as early Wisconsinan (White and Totten, 1965).

Near the mouth of the Muskingum River, S6 and S5 have higher surface elevations relative to river level than their counterparts upstream (fig. 8). The higher surfaces could be due to influx of Muskingum River outwash. Additional

Muskingum River outwash deposited at the same time or a later time would increase the volume of the Ohio River alluvium, raise the level of the floodplain, and probably effect the Ohio River flow upstream. The outwash deposits of the Muskingum River would raise the Ohio River base level resulting in a decreased gradient upstream and consequently decreased carrying capacity of the river. As a result, fine sediment, instead of sand and gravel, would be deposited for a distance upstream from the Muskingum River outwash as shown by the 15 m (50 ft) of sand just north of the Wood County boundary. In contrast, sand and gravel was deposited at the S5 level farther upstream along West Virginia's northern panhandle.

During the approximately 42,000 year interstadial between the Titusville and Kent events (Fullerton, 1986), the Ohio River alluvium probably was incised again. There is no evidence for erosion into the bedrock channel at this time. The overbank deposits of S5 and S6 were locally mantled by sand and silt windblown from the wide, flat floodplains after they were abandoned as terraces.

During the Kent advance (correlated as late Wisconsinan by White and Totten, 1965), the channel was filled with sand and gravel outwash to the level of S4, approximately 5 m (16 ft) below S5. Wood dated as 22,340 $\pm$ 960 yr. B.P. under 5.5 m (18 ft) of alluvium at McMechen is evidence for a Kent age of S4. Farther downstream at Boaz, the 13,510 $\pm$ 270 yr. B.P.

dated mammoth bone under 3 m (9 ft) of sand and gravel outwash (Fonner, 1982) indicates continued deposition of coarse sediment after the Kent and equivalent advances in the Killbuck, Cuyahoga, and Scioto sublobes retreated approximately 16,000 yr. B.P. (Fullerton, 1986). The last glacial advance to reach the headwaters of the Muskingum River occurred from approximately 15,000 to 14,300 yr. B.P. (Fullerton, 1986). The Centerburg Till in the Scioto sublobe (Root and others, 1961) and Hiram Till in the Killbuck and Cuyahoga sublobes (White, 1982) were deposited at this time. The post-Centerburg-Hiram advance date of the Boaz mammoth bone shows an approximately 800 year time lag from glacial retreat at the headwaters of the Muskingum River and deposition of the outwash at Boaz. However, this apparent time lag may be the result of intrinsic error of radiocarbon dating and the tendency of bones to date younger than their true age (Stuckenrath, 1977). The time lag, if real, was probably due to the distance of at least 96 kms (60 miles) the outwash had to be transported down the Muskingum River, its tributaries, and the Ohio River to Boaz. The younger sediment from post-Kent advances affecting the Muskingum River may have covered older outwash from upstream on the Ohio River. This may explain why the ages of Ohio River deposits downstream from the Muskingum River's mouth are non-synchronous with equivalent deposits underlying S4, and possibly S3, S5, and S6 upstream on the Ohio River.

Therefore, the Ohio River surfaces downstream from the Muskingum River may not be correlative with those upstream.

A new floodplain, S3, was deposited below the late Wisconsinan Kent-age S4, abandoning S4 as a terrace in the process. After abandonment, S4 was locally mantled by wind-blown deposits. S3 is probably late Wisconsinan in age, based on position below the Kent-aged S4 and above the Holocene-aged S2. The very early Holocene date (9750 $\pm$ 200 yr. B.P.) from wood under 5.5 m (18 ft) of sand and gravel at the Pike Island Lock and Dam S2 site indicates that the higher (and presumably older) S3 surface was probably deposited before the beginning of the Holocene. Correlation of the Chili series soils of S3, and the S3 level at Chester to the Kent advance, (Lessig, 1961b; White 1982; White and Totten, 1985) further substantiates the late Wisconsinan age assignment.

The Ohio River probably migrated laterally and vertically in the valley incising and reworking sediment during the Holocene. In the process, S2 was deposited approximately 4 m (12 ft) lower than S3. S3 remained as a floodplain receiving overbank sediments (fine-grained Ohio River alluvium) during higher annual floods. Without glacial meltwater during the Holocene, the river volume and velocity decreased and thick deposits of fine-grained Ohio River alluvium began to accumulate on the channel deposits of S2 and S3. As the Ohio River continued to incise during the

Holocene, S2 was left as a high floodplain receiving fine-grained Ohio River alluvium during higher annual floods and S3 was left as a third floodplain occasionally receiving overbank sediments. The 9750 ± 200 yr. B.P. wood at Pike Island (Philbrick, 1961) under 5.5 m (18 ft) of coarse-grained Ohio River alluvium (Gray and others, 1979) shows continued reworking of the coarse alluvium during the Holocene. Downstream from the Muskingum River, the 5,000 ± 70 yr. B.P. and 5120 ± 300 yr. B.P. dated wood buried by 4 m (13 ft) of sand and gravel below S2, shows reworking of the coarse sediment later in the Holocene.

S1, and S0 formed by the same process of gradual incision and progressive overbank deposition during the Holocene. S1 is about 6 m (20 ft) decreasing to about 3 m (6 ft) below S2 (fig. 8), S0 is about 4 m (14 ft) below S1 and about 6 m (18 ft) a.l.w. of the Ohio River. The Ohio River still flows over about 3 to 9 m (10 to 30 ft) of coarse-grained Ohio River alluvium as shown by lock and dam core holes (U.S.G.S. unpublished data, Morgantown, West Virginia). All three floodplains and terrace S3 still accumulate overbank sediment during floods: S0 several times a year, S1 once every three or four years, S2 occasionally, and S3 only during record and near-record high floods. S0, S1, and S2 have accumulated an average of 7.7 m (25 ft) of overbank sediments whereas S3 averages a 5 m (16 ft) accumulation (see Appendix II for core hole numbers).

CHAPTER 6

SUMMARY, DISCUSSION, AND CONTRIBUTIONS

SUMMARY

In summary, the late Pleistocene history of the upper Ohio River Valley floodplains and terraces is complex. Four tributaries (Allegheny River, Beaver River, Little Beaver Creek, and Muskingum River) drained four glacial sublobes, (Grand River, Killbuck, Cuyahoga, and Scioto) during the early Wisconsinan Titusville advance and late Wisconsinan Kent advance. Each glaciated tributary added outwash to the Ohio River at different levels and, for the Muskingum River, possibly at different times than the others. The Ohio River adjusted to each new influx of coarse sediment and readjusted after glacial recession by reworking the previously deposited alluvium. As a result, eight fluvial surfaces formed in the upper Ohio River Valley. The uppermost, terraces S6 and S5, may be Titusville in age, as inferred from their position above a very early Kent radiocarbon date on S4. Terrace S7, at the same level as a segment of S5, is probably pre-Titusville, possibly Sangamonian, based on a morphologic relationship to S6, S5, and Illinoian terraces. The lower terraces, S4 and S3, are late Wisconsinan-aged, based on radiocarbon dates at McMechen and Boaz. S2, S1, and S0 are Holocene-aged, as shown by radiocarbon dates at Pike Island Lock and Dam and Blennerhassett Island.

As age and height of the surfaces above river level increases, soil development generally increases. The first floodplains, Holocene S0 and S1, have only incipient soil formation due to frequent interruptions from deposition of new flood sediment. Their strongest horizon is a B with no clay accumulation and only a slight change in color from the A horizon. On the higher Holocene floodplain of S2, soils formed in the overbank deposits have a weak but definite clay accumulation in a Bt or Bx horizon. Soils formed in the sand and gravel on that surface have a moderate amount of clay accumulated in a Bt horizon. The late Wisconsinan Kent-aged S3, on the other hand, is so rarely flooded that soil formation is seldom interrupted. The S3 and S4 (also Kent-aged) terrace soils have a weakly to moderately developed profile with a Bt or Bx in the sand and gravel, overbank deposits, and silt of probable eolian deposition. However, the well sorted sands of possible eolian origin have a poorly developed profile due to their texture. The Chili series of Columbiana County, Ohio can generally be used to correlate the S3 and S4 surfaces to the late Wisconsinan advance (Lessig, 1961b). The soils of the early Wisconsinan Titusville terraces, S5 and S6, are characterized by the Negley series in Columbiana County, Ohio, which has a more well-developed soil profile and a thicker Bt horizon than the Chili series. The Negley series of Columbiana County, Ohio can generally be used to correlate S5 and S6 surfaces to the

early Wisconsinan Titusville advance. Again, the sandy soils have poor profile development due to their texture. S7 is a terrace segment at Beech Bottom with a much more developed soil profile than S6 and S5, possibly due to a Sangamonian age.

All surfaces at the same height are not necessarily the same age. The S7 surface at the Weirton abandoned channel and Beech Bottom are at the same elevation as nearby S5 surfaces, but are probably older (Sangamonian rather than early Wisconsinan). The surfaces on the Ohio River below the mouth of the Muskingum River are covered with younger sediment from that tributary, as shown by the 13,510 $\pm$ 270 yr. B.P. date on the Boaz mammoth bone underlying S4. Upstream at McMechen, the 22,340 $\pm$ 960 yr. B.P. date underlying S4 shows a late Wisconsinan Kent age. The age discrepancy may be from younger Muskingum River outwash covering older Ohio River outwash below the mouth of the Muskingum River. Therefore, Ohio River surfaces downstream from the mouth of the Muskingum River may not be correlative to those upstream on the Ohio River.

The thick, fining-upward deposit underlying each surface consist of a combination of five facies that commonly overlap and interbed. The coarsest, most dominant facies, coarse-grained Ohio River alluvium, is composed of well-rounded gravels (mostly sandstone clasts with about 5% Canadian Shield erratics) and sand. Much of the sediment in

this facies is outwash deposited by a braided stream. Tributary alluvium, composed of sand and gravel with more sand and silt than coarse-grained Ohio River alluvium, occurs as local lenses within outwash and reworked outwash. Colluvium, composed largely of angular sandstone clasts with more shale clasts and silt and clay than the other coarse facies, interfingers with alluvium at the valley walls. Fine-grained Ohio River alluvium composed of overbank sand, silt, and clay caps the coarse deposits. Irregular mantles of sand and silt probably represent an eolian facies.

The texture of near-surface deposits in S2 through S6 fines downstream; from coarse-grained Ohio River alluvium facies in the northern counties of Beaver (Pennsylvania) and Columbiana (Ohio) to fine-grained Ohio River alluvium to the mouth of the Muskingum River. At that point, the surfaces of S4, S5, and S6 are either eolian or alluvial sand or coarse-grained Ohio River alluvium. S2 and S3 are still covered with fine-grained Ohio River alluvium. S0 and S1 are covered by fine-grained Ohio River alluvium in the entire study area. Overall grain size of the coarse-grained Ohio River alluvium facies along West Virginia's northern panhandle also decreases downstream. Within this facies, roundness, and sphericity in the 2.00 mm and 6.35 mm gravels increases downstream.

Height of the surfaces a.l.w. changes downstream with increasing distance from the outwash source. A steep

gradient at the mouth of glaciated tributaries causes the surface elevation of S6 through S3 to decline about 5 to 6 m (15 to 20 ft) for 64 to 81 km (40 or 50 miles) before leveling (fig. 8). Each of these surface levels rise about 2 m (6 ft) before the mouth of the Muskingum River, probably from additional Muskingum River outwash, and maintain that height to the end of the study area. S2 also has a steep gradient at the mouth of the northern glaciated tributaries causing the surface to decline approximately 3 m (10 ft) before leveling. However, S2 does not rise near the Muskingum River. The absence of a rise in the surface level is probably due to lack of outwash or reworked outwash from the Muskingum River during the Holocene. Jacobson and others (1988) also noted steeper gradients on the Ohio River at the mouths of the glacier draining tributaries. S1 and S0 maintain the same height a.l.w. for the entire study area from a constant gradient, indicating the river was eroding through alluvial fill and depositing overbank sediment during the Holocene, rather than glacial outwash.

DISCUSSION

The terraces are probably products of episodic phenomena as well as incision. As the Titusville age and Kent age glaciers melted, large, thick deposits of coarse-grained outwash were transported by braided streams to the mouth of each glacier draining tributary. With the increased

gradient from the thick deposits and the added volume of meltwater, the braided stream was able to carry cobbles and boulders downstream on the Ohio River. The coarser gravels were deposited when the gradient was too low for the Ohio River to carry them, whereas the finer sizes were carried farther downstream. With glacial retreat, sediment load decreased and the response of the Ohio River and the glaciated tributaries was to incise into the alluvial deposits. At this time, the streams migrated, laterally and vertically, to rework and redeposit floodplain material.

Incision could have also been a result of increased gradient by lowering of a local base level. An important base level change was at the mouth of the Muskingum River. As interpreted from the thick sands of S5 just north of the Wood County line, partial blockage by the Muskingum River outwash occurred at least once during Wisconsinan glaciations. After the Ohio River eroded through the outwash, the local base level was lowered on the Ohio River, and the Ohio River and its tributaries incised. Incision continued up tributaries as the system adjusted to the change in the master stream gradient.

The glacial advances and retreats of the early- and late-Wisconsinan, successive phases of alluvial fills, probable local base level controls, and incision created the complex set of terraces present on the Ohio River. In general, each younger deposit is inset in the bench formed by

previous incision. The depositional history is complicated by the younger alluvium from the Muskingum River covering the older deposits from upstream on the Ohio River. The end result is unpaired terraces and floodplains from temporary pauses of incision during lateral and vertical downcutting of the channel. During the Holocene, the graded Ohio River continued to adjust and build up thick overbank deposits on S0, S1, and S2 without the large influx of outwash in the present dynamic equilibrium (Schumm, 1977) of the system.

CONTRIBUTIONS

I contributed to the geologic history of the upper Ohio River Valley by making a more detailed study of the Ohio River surfaces and deposits than any previously published work. I accomplished my goals of characterizing the late Pleistocene and Holocene fluvial surfaces in the 266 km (165 mile) reach of the upper Ohio River Valley and glaciated tributaries. During the course of study, five terraces and three floodplains were identified within 40 m (130 ft) of pre-dam low water level of the Ohio River. Each of the surfaces was characterized vertically and downstream by stratigraphy within the deposit, and soil development. Soil profile development was characterized by one soil profile on S7, a small number of complete soil profiles on S5 (S4 profiles were incomplete), and information published by U. S. D. A. Soil Conservation Service county soil surveys. Five

facies of the valley fill were identified and characterized in the field and verified by sieve analysis and pebble counts. The laboratory analysis also documented a downstream decrease in grain size, and an increase in Canadian Shield erratics and chert for the outwash facies along West Virginia's northern panhandle.

Surfaces were correlated to glacial advances or interglacial stages and the Holocene by combining several methods: tracing surfaces downstream from the early Wisconsinan Titusville age and late Wisconsinan Kent age tills, stratigraphy, soil development, altitude of bedrock floor, height of the surface a.l.w., and known radiocarbon dates. All of the information just described was used to develop a model of the stratigraphy and depositional facies of lower surfaces in the upper Ohio River Valley.

My analysis of the geologic history of the upper Ohio River Valley generally agrees with those of Lessig (1959b, 1961a, 1961b), White (1982), White and Totten (1985), Jacobson (1985), and Jacobson and others (1988) with a few exceptions. First, I segregated each of their single levels of early Wisconsinan, late Wisconsinan, and Holocene surfaces into two, two, and three levels, respectively. Close examination of floodplain and terrace rises and flats in this study indicated that more levels were present than previously shown. Second, although most surfaces that I identified fall within their range of elevations for each age, S4 and S2 do

not. Radiocarbon dates for S4 and S2 show a younger age for each surface: S4 was deposited during the late Wisconsinan Kent advance, not early Wisconsinan Titusville advance, and S2 was deposited during the Holocene advance, not the late Wisconsinan Kent advance. Third, segments of an older channel floor and alluvial fill at the same level as the early Wisconsinan S5 were first identifed and tentatively dated as Sangamonian.

FUTURE WORK

Suggestions for future work to further categorize these levels and refine the geologic history includes: obtain core hole data from private companies for more complete channel morphology, field and laboratory study of complete soil profiles of all surfaces rather than three, and more radiocarbon dates. Continuing the correlation of the surfaces upstream and downstream from the study area would also help complete the geologic history picture.

Attachments

Attachment B-1. Local Landfill Monitor Well Geologic Logs and Technical Specifications
Attachment B-2. Historic Borehole, Test Well and Production Well Geologic Logs

Borehole geologic logs of the 12 boreholes completed at the River Bank Landfill, the three boreholes drilled at the Anaerobic Digestion Ponds and the seven boreholes drilled at the Burning Grounds are presented on Figures B-1 through B-22. Well completion logs for the Local Landfill monitor wells LLMW 1 through LLMW 8 (completed in 1989), are also included as Attachment B-1. Geologic logs of test borings from previous investigations are presented in Attachment B-2. The field geologic logs for the temporary well completions are included in Appendix E.

DRILLING, TEMPORARY MONITOR WELL INSTALLATION AND SOIL SAMPLING

Du Pont contracted H.C. Nutting of Charleston, West Virginia to drill, install and abandon the 22 temporary monitor wells. The boreholes were drilled with a CME model 55 mechanically driven rotary unit with torque converter, using 4-inch inner diameter, 5-foot long hollow stem auger flights. Composite samples were collected at 5 foot intervals with 24-inch long, 2-inch diameter split-spoon samplers at the Anaerobic Digestion Ponds and Burning Grounds, and 5 to 10 foot intervals at the Riverbank Landfill, and wherever significant lithologic changes occurred.

The auger flights were steam cleaned between each borehole to prevent potential cross-contamination. All water used to clean auger flights was collected in a plastic lined sump and pumped into drums and/or a tanker for proper disposal. Split spoons were cleaned between samples with Alconox detergent wash and tap water rinse. Split spoon samplers that were used for collection of samples for laboratory analysis were cleaned with an additional 10% nitric acid wash, distilled water rinse, 50% methanol wash and distilled water rinse. All washwater, waste nitric acid wash and rinse water and waste methanol wash and rinse water were collected in separate containers and properly characterized, treated and/or disposed.

The temporary monitor wells were constructed of 2-inch inner diameter schedule 40 flush-joint threaded PVC casing, with 10 feet of 0.01-inch slot PVC screen and a threaded PVC end-cap at the base. A steel plate was fitted around the top of each well casing and installed in the annular space of the borehole at a depth of 5 to 7 inches below grade. The upper part of the wells were sealed with bentonite pellets along the annulus of the borehole, from the steel plate to grade level. The bentonite was mounded above grade around the PVC riser to a height of approximately eight inches. The bentonite and steel plates were used to seal the top of the borings to prevent any surface water runoff down along the annular space. The 2 to 3 foot PVC risers were capped with locking well caps.

Drilling and monitor well installation and abandonment were supervised by Libby Alberti, a hydrogeologist with Du Pont Environmental Remediation Services (DERS). The borings were geologically logged and monitored for organic vapors using an HNU

photoionizing detector (PID) or organic vapor analyzer (OVA). The recorded PID or OVA values from drill cuttings and split spoon samples are indicated on both the written and pictorial logs. Geologic logs were prepared based on split spoon samples and drill cuttings. Subsurface materials were classified based on the Unified Soil Classification System (USCS).

The temporary monitor wells were abandoned in March 1992 per the original project schedule. Well abandonment was completed by H. C. Nutting under the supervision of Libby Alberti. Well abandonment was accomplished by first removing the bottom well casing cap and then tremieing cement, bentonite and grout into the the surrounding formation. Well casings were either removed during the grouting process or left in place and perforated to allow grout penetration into the surrounding formation.

Surficial (shallow) soil samples taken at the Local Landfill, Polyacetal Waste Incinerator and at the plant background locations were obtained with a stainless steel hand auger or a steel shovel.

GEOLOGIC LOGS

Riverbank Landfill North

Boring logs for the temporary monitor wells installed to the north of the Riverbank Landfill along the banks of the Ohio River are shown in Figures B-1, B-4, B-6, B-7, B-10 and B-11. The subsurface materials adjacent to the riverbank in the upper 29 to 36 feet consist of clay and silt. This upper clay and silt zone is underlain by silty, clayey or gravelly sand. The depth to ground water during drilling was approximately 18 to 29 feet at RBLMW 1, 4, 7, 10 and 11, and 9 feet at RBLMW 6. Static water levels measured on 12/12/91 were about 10 to 29 feet deep.

The six northern Riverbank wells were completed about 1 to 3 feet below the base of the clay layer, with completion depths of about 30 to 39 feet. The wells had 1 to 3 feet of well screen in sand and 7 to 9 feet of well screen in the overlying clay or silt. This interval was chosen to intercept the top of the highly permeable sand unit as well as the ground water in the overlying saturated clays and silts.

An HNU photoionizing detector was used to monitor any organic vapors encountered during the drilling of monitor wells RBLMW 10 and RBLMW 11. Due to a malfunction in the HNU as a result of water damage, an OVA was subsequently used to monitor any organic vapors encountered while drilling wells RBLMW 7, 6, 4 and 1. Split spoon samples, drill cuttings and the top of the borehole were monitored for organic vapors. Results are shown on the geologic logs. In general, the samples from the surface to about 20 to 30 feet deep had HNU and OVA readings equivalent to background. Deeper samples, taken from 30 to 40 feet, had HNU and OVA readings approximately 1 ppm above background. The highest

OVA reading in the northern Riverbank Landfill wells was 6.2 ppm at RBLMW 4, at a depth of 20 to 22 feet. However, no volatile or semi-volatile organics were detected in the ground water at RBLMW 4, indicating that this OVA measurement may not have been representative of actual conditions. The two farthest upgradient wells, RBLMW 10 and 11, had background readings over their entire depths. There did not appear to be any systematic change in PID or OVA readings at the water table at any of the northern Riverbank Landfill wells.

Riverbank Landfill South

Boring logs for the temporary monitor wells installed to the south of the Riverbank Landfill and above the Ohio River bank are shown in Figures B-2, B-3, B-5, B-8, B-9 and B-12. The subsurface materials consist of approximately 10 to 15 feet of clayey silt and/or silty sand underlain by sandy gravel grading into sand. Some borings had 1 to 5 feet of fill material at the surface which consisted of rock and concrete debris and/or what appeared to be ash.

Based on the drill cuttings, the gravel unit beneath the silt and sand consisted of 2 to 4-inch diameter, well rounded, sub-spherical cobbles in a brown sand matrix. Because of the large cobbles encountered (> 2-inch diameter), split spoon samples taken in this zone were not representative. The large cobbles were not introduced into the sampler as readily as sand and smaller gravel.

Throughout the sand and gravel unit, the amount and size of gravel generally decreased with depth, grading from sandy gravel through gravelly sand to well-sorted sand. The gravel generally disappeared or appeared only in trace amounts at a depth of about 40 to 50 feet. Occasional 1/8 to 2.5-inch wide bands of what appeared to be black peat or orange rust staining were encountered.

The depth to ground water was about 60 to 61 feet in the eastern portion at RBLMW 9 and 12, and at about 65 to 66 feet in the western portion at RBLMW 2 and 3. Ground water was encountered at slightly deeper levels (67 to 69 feet) at RBLMW 8 and 5, in the vicinity of the Ranney process water production well. Flowing sand was encountered below the water table in all borings south of the Riverbank Landfill. To prevent the sand from flowing up the augers, domestic water had to be used while drilling and pulling the rods below the water table. The water was taken from the site drinking water supply lines.

The temporary wells were screened across the ground water/vadose zone interface, with about 9 feet of well screen below the water table and about one foot of well screen in the unsaturated zone. Completion depths ranged from 69 to 79 feet.

With the exception of RBLMW 2, PID readings on split spoon samples, drill cuttings and down boreholes were all at background, or less than 1 ppm above background. PID readings from split spoon samples at RBLMW 2 varied between background level at the surface to 62 ppm at the ground water interface at a depth of 65 feet. The average PID reading was about 5 ppm. Drill cuttings and down-hole PID readings from RBLMW 2 were similar, but PID levels dropped off dramatically away from the borehole to levels slightly above background in the breathing zone.

The hydraulic gradient across the Riverbank Landfill, from wells near the southern boundary to the wells on the northern side, is approximately 0.03 ft./ft. to the south (away from the river). This value was calculated based on static ground water levels measured on 12/12/91. The topographic gradient across the Riverbank Landfill is approximately 0.17 ft./ft. in the opposite direction, towards the river.

Anaerobic Digestion Ponds

Boring logs for the three temporary monitor wells at the Anaerobic Digestion Ponds are shown in Figures B-13, B-14 and B-15. The subsurface materials in the vicinity of the old Anaerobic Digestion Ponds consist primarily of 20 to 25 feet of silt and clay overlying 15 feet of sand and/or silty sand. The depth to ground water was about 29 to 31 feet. The wells were screened across the ground water/vadose zone interface, with completion depths of 35 to 37 feet. The wells had about 5 to 7 feet of well screen below the water table and about 3 to 5 feet of well screen above it.

PID levels from split spoon samples, drill cuttings and the top of the boreholes were consistently at background or < 1 ppm above background. In ADPMW 2, white-gray fragments which appeared to be teflon* were encountered at a depth of 10 to 12 feet, and similar material was encountered from 5 to 12 feet in ADPMW 3. In both instances there was an odor similiar to the odor of the waste material which was disposed of in the Anaerobic Digestion Ponds.

Polyacetal Waste Incinerator

The shallow (0 to 2 feet) subsurface materials in the vicinity of the Polyacetal Waste Incinerator consist of brown gravelly clayey silt and silty sand. The PID readings for the two soil samples and boreholes were background.

Burning Grounds

Boring logs for the seven temporary monitor wells completed at the Burning Grounds are shown in Figures B-16 through B-22. The subsurface materials in the vicinity of the Burning Grounds are similar to those found south of the Riverbank Landfill. The upper 10 to 20 feet consist primarily of silt and/or silty sand. This unit is underlain by gravelly sand which grades into well

sorted sand at a depth of approximately 40 to 45 feet. Occasional 1/4 inch to 1 foot thick zones of what appeared to be black peat or ash were present within the gravel and sand units.

Ground water was encountered at a depth of 59 to 62 feet. Flowing sand was encountered below the water table. Domestic water was used to drill to about 9 feet below the water table, with completion depths of 68 to 70 feet below ground surface. The wells were screened across the ground water/vadose zone interface, with approximately 9 feet of well screen below the water table, and approximately 1 foot of well screen above it.

PID levels from split spoon samples, drill cuttings and the top of the boreholes were < 1 ppm above background for all borings except BGMW 5. The maximum PID reading from split spoon samples from BGMW 5 was 20 ppm at the 0 to 2 foot depth. The readings generally decreased with depth, reaching background levels at a depth of 60 feet. However, no volatile or semi-volatile organics were detected in the ground water at BGMW 5. Only low levels of methylene chloride were detected in the shallow soil samples.

Local Landfill

Geologic logs and technical specifications for the eight Local Landfill monitor wells are included as Attachment B-1. Cross sections G-G′ and H-H′ through the Local Landfill are presented on Figures B-23 and B-24.

The Local Landfill monitor wells were constructed in 1989 by the firm of Tetra-Tech Richardson. The wells were screened over 15 to 20 foot intervals in either the shallow weathered zone or sandstone zone, both of the Dunkard Group. Additional geologic information is included in Appendix D of the VI Work Plan. No additional drilling was conducted for the VI.

Monitor wells LLMW 1, 2, 3, 5 and 7 are located in topographic lows and are only 21 to 39 feet deep. Boring logs indicate that the subsurface materials consist of an overburden of clay with some sand layers, a zone of highly weathered shale, and competent bedrock of the Dunkard Group. The shallow clay layer which starts at ground surface ranges in thickness from 3 feet at LLMW 1 to 25 feet at LLMW 5 and also contains some minor sandy and silty zones. Underlying the clay layer is weathered shale which ranges in thickness from 10 feet thick in LLMW 5 to 35 feet thick in LLMW 1. Competent bedrock is present at depths ranging from 21 feet at LLMW 3 to 40 feet at LLMW 1. The bedrock at these sites consists of red and gray shale with minor sandstone and siltstone beds.

The depth to ground water in the shallow weathered zone ranges from 4 to 20 feet below ground surface. The shallow monitor wells are screened in the clay and weathered shale zones. Well yields are very low, from <0.05 gpm to 1 gpm.

Monitor wells LLMW 4, 6 and 8 are located at higher elevations. They are 90 to 155 feet deep and are completed in a locally laterally continuous sandstone unit. The subsurface materials encountered at these sites consist of about 0 to 32 feet of clay, sand and weathered shale overlying competent bedrock of the Dunkard Group. The bedrock consists primarily of thick beds of red and gray shale with minor sandstone and siltstone beds. The sandstone in which the wells are completed occurs at an elevation of approximately 725 to 735 feet msl and ranges in thickness from 15 feet at LLMW 6 to 20 feet at LLMW 8. The top of the sandstone unit is about 60 feet below ground surface at LLMW 6, and about 110 to 120 feet below ground surface at LLMW 4 and 8.

The depth to ground water in these deeper wells completed in the sandstone unit ranges from about 65.8 feet below ground surface in LLMW 8 to 130 feet below ground surface in LLMW 4. These wells only yield about 0.5 to 1.5 gpm. This is consistent with the low yields typically observed from the Dunkard Group.

Historic Borehole Geologic Logs

Geologic logs for historic test borings drilled for geotechnical purposes, production wells and test wells are included in Attachment B-2. The subsurface materials depicted in the VI geologic logs are in close agreement with the historic geologic logs. The historic borings from the plant area show a clayey or sandy silt unit overlying gravel and sand. The borings from the riverbank indicate over twenty feet of silty, sandy or gravelly clay overlying sand and/or gravel. The historic borings that were advanced to bedrock (BD-41, BD-44 and BD-46) show that the floor of the Ohio River Valley basin in the vicinity of the plant consists of gray, black and/or brown weathered shale of the Dunkard Group. The bedrock/ overburden contact is at an elevation of about 530 to 540 feet msl.

Upgradient Soil Samples

Upgradient soil samples UGS 1 and UGS 4 were taken from the west end of the plant and were composited from a depth of 0 to 2 feet. The soils consisted of brown clayey silt. Upgradient soil samples UGS 2 and UGS 3 were taken from the east end of the plant. UGS 2 was composited from a depth of 2 to 4 feet. This depth was chosen because the subsurface material from the surface to 2 feet deep was dark brown topsoil fill which did not appear to be representative of soil at the plant. Native material (brown clayey silt) was encountered below 2 feet. UGS 3 was composited from a depth of 0 to 2 feet. The PID readings for UGS 1 and UGS 2 were background. No PID readings were taken at UGS 3 and 4. Background soil sample UGS 564 was taken at a private residence about 2.5 miles east of the plant. The location was a hill and the soil consisted of brown silty topsoil. Offsite soil samples were also taken at DERC Park, located approximately 4 miles west of the Washington Works plant and from a private residence in the

town of St. Marys, located approximately 30 miles east-northeast of the Washington Works plant along the Ohio River.

Re: Wellhead Protection Survey

Dear Mr. Toomey,

Please accept our enclosed Wellhead Protection Area Survey. With the assistance of Mr. Baker of WV Rural Water, we have inventoried the potential sources of groundwater contamination within the Wellhead Protection Area delineated by your office in 1994. Within this protection area the potential sources which cause the greatest concern include possible spills on the railroad tracks adjacent to our wells, and possible dredging of the riverbed next to them.

Also, we have added a Secondary Protection Area which includes the watershed of a small tributary stream of the Ohio River. This stream enters the Ohio River very near our wellfield, and due to concern over past spills to this stream we have included it in our protection plan. There are a number of industrial sites within this secondary area, including landfills.

Lubeck PSD has received approval from your office for other parts of our protection plan. We trust this update of our survey will meet with your approval as well. Please advise if there is anything else we may do to update the overall plan.

Sincerely,

James M. Cox

WEST VIRGINIA RURAL WATER ASSOCIATION

July 23, 1991

Mr. Gary Viola, PE
Environmental Engineering Division
Office of Environmental Health
Capitol Complex Bldg. 3, Room 550
Charleston, West Virginia 25305

Dear ~~Mr. Viola:~~ Gary

Enclosed is an application for the delineation of a wellhead protection area for Lubeck Public Service District.

The Lubeck PSD Board met on April 25, 1991 and voted to develop a wellhead protection plan for their new well field. They requested that WV Rural Water Association assist them in developing this plan.

Please contact me at 344-5593 if you have any questions on the application or need further information on the wells.

Sincerely,

Chet Fleming

Chet Fleming
Ground Water Technician

Member of NATIONAL RURAL WATER ASSOCIATION

APPLICATION FOR WELLHEAD PROTECTION AREA DELINEATION

Name of Water System: LUBECK PUBLIC SERVICE DISTRICT

Mailing Address: POST OFFICE BOX 700

City, State & ZIP: WASHINGTON, WV 26181

Telephone Number: (304) 863-3341 PWSID #

Primary Contact: CHET FLEMING Tel. No. 757-0985

INSTRUCTIONS

A separate application shall be submitted for each well or group of wells located more than 500 feet from others wells to be protected. Complete a "Well Data Sheet" for each well covered by this form. Enclose a copy of any technical data available on each well. i.e Well Permit, Driller's Well Logs, Pumping Tests and Well Renovation Record. Attach a USGS 7.5' Topographical Map with each well marked on it with well identification shown.

GENERAL INFORMATION

County where well(s) are located: WOOD

Number of wells operated by system: SIX (6)

CONCLUSIONS

1. Three 12" x 26" gravel packed wells were drilled at the Sandy Creek well field as a part of this project. Total depth of the wells ranged between 62 to 67 feet. The wells are developed in sands and gravel immediately overlying the bedrock.

2. Screen lengths and slot sizes for the three new wells are as follows: PW-A, 15 feet of 75 slot; PW-C, 10 feet of 110 slot; and PW-D, 17 feet of 40 slot.

3. Variable rate step tests and 24-hour constant rate tests were conducted at each well. Evaluation of the data indicated the wells have the following safe capacities: PW-A, 375 gallons per minute (gpm); PW-C, 250 gpm; and PW-D, 250 gpm. These rates assume all three wells and existing well PW-B are operating simultaneously.

4. Total capacity of the four wells at the tested site is 1,250 gpm or 1.8 million gallons per day (mgd). This figure includes 375 gpm from existing well PW-B.

5. Lubeck's 1987 average daily water demand was 0.86 mgd while daily peak usage was as high as 1.26 mgd. Both of these flow rates can be supplied with two or three wells. Flow from wells PW-A and PW-C, and/or PW-B and PW-D, will equal 0.9 mgd. The capacity of three wells is 1.26 or 1.44 mgd depending upon if the third well has a capacity of 375 gpm or 250 gpm.

6. Both average daily and peak day water usage can be supplied with the largest capacity well at the site out of service. This will allow normal water usage even if an emergency outage occurs and/or well maintenance is required.

7. One water sample was collected and analyzed from each of the three new wells. Iron at PW-A, iron at PW-C, and iron and manganese at PW-D exceeded applicable Secondary U.S. Environmental Protection Agency (U.S. EPA) Drinking Water Standards. Analytical procedures used for mercury analyses at PW-C were insufficient to meet the drinking water

FILE

RECOMMENDATIONS

1. It is recommended, as water usage dictates, that wells PW-A, PW-C, and PW-D be equipped with submersible pumps and motors, similar to existing well PW-B. The total dynamic head (TDH) of the future pumps will likewise be similar to that of the pump in well PW-B, which has a head of 430 feet.

2. Wells PW-A and PW-C should be operated in unison, or wells PW-B and PW-D should be operated in unison, to meet average daily demand. The two well combinations should be operated for 1-week cycles. When daily peak usage occurs, the increased demand can be furnished using system storage and/or pumpage from a third well at the site.

TEST DRILLING AND SITE SPECIFIC GEOLOGY

Site specific geology was determined based on drillers' well logs and sieve analysis data. Drillers' well logs address subsurface conditions the full depth of unconsolidated materials. Subsurface conditions at each well are discussed below. Drillers' well logs, sieve data, and miscellaneous drillers' reports are shown in Appendix A. All wells installed as a part of this project were drilled with cable tool drilling equipment. The water supply wells were drilled as 26-inch diameter boreholes, while the test wells were drilled as 10-inch diameter boreholes.

Production Well PW-A

Test well TW-A was drilled in late January 1988 and production well PW-A was completed the following month. TW-A is approximately 16 feet north of PW-A. PW-A is 101 feet east of the Ohio River bank, 160 feet west of the railroad track, and roughly 300 feet north of PW-B. Subsurface conditions at the well based on the log for TW-A are described below:

0 to 1 foot - Topsoil
1 to 28 feet - Brown sandy clay
28 to 39 feet - Gray clay
39 to 46 feet - Clay and gravel
46 to 66.5 feet - Sand and gravel
66.5 feet - Bedrock

The total depth of test well TW-A is 66.5 feet with the screen set at 61.5 to 66.5 feet. The well is equipped with 6-inch diameter steel casing and 6-inch diameter polyvinyl chloride (PVC) screen. Static water level at the time of drilling was measured at 15 feet below the top of the casing.

The total depth of well PW-A is 66.5 feet with the screen set at 51.5 to 66.5 feet below ground. Thirty-three feet of 26-inch diameter steel casing, 51.5 feet of 12-inch diameter steel casing, and 15 feet of 12-inch diameter 75 slot stainless steel screen were installed at the well. The gravel pack consisted of 1/8" x 1/16" (No. 4) Parry quartz.

Particle size analysis was performed at TW-A on six soil samples collected from 39 feet to 66.5 feet. Gradation curves shown in Appendix A indicate that the sieved material is predominantly medium to coarse sand.

Production Well PW-C

TW-C was drilled in late October 1987 and PW-C was drilled in January 1988. TW-C is approximately 16 feet north of PW-C. PW-C is 81 feet east of the Ohio River, 127 feet west of the railroad track, approximately 300 feet north of PW-D, and roughly 300 feet south of PW-B.

Subsurface conditions at the well based on the log for TW-C are described below:

0 to 30 feet - Brown sandy clay
30 to 40 feet - Gray sandy clay
40 to 45 feet - Gray clay and gravel
45 to 62 feet - Medium to fine sand and gravel
62 feet - Bedrock

The total depth of test well TW-C is 62 feet with the screen set at 57 to 62 feet. The well is equipped with 6-inch diameter steel casing and 6-inch diameter PVC screen. Static water level in the well as measured at the completion of drilling was approximately 15 feet below the top of the casing.

The total depth of well PW-C is 62 feet with the screen set at 52 to 62 feet below ground. Fifty-two feet of 26-inch diameter steel casing, 52 feet of 12-inch diameter steel casing, and 10 feet of 12-inch diameter 110 slot stainless steel screen were installed at the well. The gravel pack consisted of 1/4" x 1/8" Parry quartz.

Grain size analysis was performed at TW-C on five soil samples collected from 55 to 62 feet. Analysis of the sieve data indicates that from 35 to 50 feet the formation is comprised of a high percentage of finer materials. The interval from 50 to 62 feet is predominantly medium sized materials or larger.

Production Well PW-D

Test hole TH-D was drilled in early November 1987 and PW-D was drilled in mid-November 1987. PW-D was drilled directly over TH-D and 15 feet west of existing TW-D. TW-D was drilled in 1985 and identified at that time as TW-2. PW-D is about 32 feet east of the Ohio River, 102 feet west of the railroad track, and approximately 300 feet south of PW-C.

Subsurface conditions at the site based on the log for TH-D is described below:

0 to 30 feet - Brown sandy clay
30 to 37 feet - Gray sandy clay
37 to 45 feet - Clay and gravel
45 to 49 feet - Medium to fine sand and gravel
49 to 53 feet - Gray sand
53 to 67 feet - Medium to fine sand and gravel
67 feet - Bedrock

The depth of test hole TH-D was 67 feet. No casing was installed at this test hole. Subsurface conditions and formation gradation at TH-D were similar to those noted at TW-2.

The total depth of well PW-D is 67 feet with the screen set at 50 to 67 feet below ground. Forty-two feet of 26-inch diameter steel casing, 50 feet of 12-inch diameter steel casing, and 17 feet of 12-inch diameter 40 slot stainless steel screen were installed at the well. The gravel pack consisted of No. 10 x 20 (No. 5) Parry quartz.

Grain size analysis was performed at TH-D on 10 samples collected from 35 to 67 feet. Analysis indicates the interval generally between 35 and 53 feet is comprised of a high percentage of finer materials. The remaining lower portion of the aquifer is somewhat more coarse, although this zone also contains a relatively high percentage of fine materials. Subsurface conditions at PW-D are much finer than at the other developed water supply well sites in the Sandy Creek well field.

PUMPING TESTS

For evaluation of aquifer characteristics and well performance, two separate pumping tests, a constant rate and a variable rate pumping test, were conducted at PW-A, PW-C, and PW-D.

Automatic Stevens' recorders, pressure transducer recorders, and battery powered water level indicators were used to measure water levels during the pumping tests. Data obtained from the constant rate tests were analyzed by Jacobs' (1945) distance-drawdown method to evaluate aquifer characteristics.

During the pumping tests, the Ohio River stage was measured. The river stage throughout all the tests varied approximately 1.5 feet. This is an insignificant fluctuation and did not affect groundwater levels during the pumping tests. The hydrograph for the river is shown in Appendix E.

Elevations were determined for supply wells and test wells at the site based on U.S. Geodetic Survey (USGS) datum. Groundwater levels discussed in this section are based on actual elevations. Surveyed elevations are shown below:

Location	Top of Casing Elevation	Ground Elevation
PW-A	596.76	595.8
PW-C	597.28	596.3
PW-D	598.81	597.8
TW-A	597.06	595.1
TW-B	597.37	595.3
TW-C	595.85	593.9
TW-D	598.15	596.2
TW-1	593.87	592.0
TW-4	597.21	595.5

Test pumping conducted at each well is discussed below.

Production Well PW-A

The first pumping test conducted at PW-A on March 8, 1988 was a four-step variable rate test. Pumping started at 7:45 a.m. and was terminated by 1:45 p.m. the same day. The well was pumped sequentially at rates of 305 gpm, 449 gpm, 663 gpm, and 738 gpm. The duration of each pumping step was 90 minutes each. The static water level at PW-A prior to pumping was measured at 583 feet. During the test, water level measurements were monitored at the pumping well and wells TW-A, TW-B, TW-C, TW-D, and TW-1. Hydrographs for these wells are shown in Appendix B. Observation of the step test hydrograph at PW-A shows that after each pumping increment, the water level stabilizes in a short time.

The second test performed was a 24-hour constant rate test during which PW-A was pumped at 600 gpm. Pumping started at 5:45 p.m. on March 8, 1988 and continued until 5:51 p.m. the next day. The static water elevation at PW-A prior to pumping was measured at approximately 583 feet. During the test, water levels in wells TW-A, TW-B, TW-C, TW-D, TW-1, and pumping well PW-A were monitored. Hydrographs of the pumping and observation wells are given in Appendix B. Observation of the constant rate hydrograph for PW-A indicates that the drawdown stabilized quickly after pumping began. Distance-drawdown analysis for PW-A was performed by analyzing drawdown data collected at the end of the test. Distance-drawdown analysis indicates that the transmissivity value was approximately 41,000 gallons per day per foot (gpd/ft). The storage coefficient was 0.0026. The specific capacity of PW-A was roughly 22 gallons per minute per foot of drawdown (gpm/ft dd). Water level in the pumping well rose to the static level after 1 hour of termination of pumping.

Production Well PW-C

The first test at PW-C was a six-step variable rate pumping test conducted on March 14, 1988. Pumping started at 2:18 p.m. and terminated at 7:30 p.m. The first five steps were pumped at 200, 300, 402, 506, and 550 gpm for durations of approximately 60 minutes each. The final step at 600 gpm was maintained for approximately 15 minutes at which time the test was discontinued to prevent the pump from breaking suction. The static water elevation at PW-C, measured prior to pumping, was approximately 580 feet.

During the test, water levels were monitored at PW-C and observation well TW-C. Hydrographs generated during the course of testing at PW-C are given in Appendix C. Observation of the step test hydrograph for PW-C indicates that after each pumping rate water levels stabilized quickly.

The second test performed was the 24-hour constant rate test during which PW-C was pumped at 500 gpm. Pumping started at 9:32 a.m. on March 15, 1988 and terminated at 9:32 a.m. on March 16, 1988. The static water elevation prior to pumping was measured at approximately 581 feet. Groundwater levels in the pumping well and wells TW-A, TW-B, TW-C, TW-D, TW-1, and TW-4 were monitored during the test. Hydrographs for the wells are shown in Appendix C. The hydrograph for the constant rate test indicates that drawdown at PW-C stabilized quickly after pumping began. Distance-drawdown analysis for PW-C was performed by analyzing drawdown data collected at the end of the test. The data indicates the transmissivity value was approximately 32,000 gpd/ft. The storage coefficient was 0.0021 and the specific capacity at the end of the test was roughly 17 gpm/ft dd. Water level in the pumping well rose to approximately 2 feet of the prepumping level within 2 hours after cessation of pumping.

Production Well PW-D

A six-step variable rate pumping test was conducted at PW-D on March 17, 1988. The pumping started at 8:15 a.m. and terminated at 2:15 p.m. the same day. The well was pumped at 150, 226, 302, 377, 450, and 528 gpm for a duration of 60 minutes each. Static water elevation at PW-D measured prior to pumping was 581 feet. During the course of the test, water levels were monitored in PW-D, TW-A, TW-B, TW-D, TW-1, and TW-4. Hydrographs generated at these wells during the test are given in Appendix D. As can be seen on the hydrograph for PW-D, the water level stabilized during each step.

The second test was a 24-hour constant rate test which began on March 21, 1988, with continuous pumping at 400 gpm. Pumping started at 10:30 a.m. and continued until 10:36 a.m. the following day. Prior to the test, the static water elevation at PW-D was measured at 581 feet. During the test, water level elevations were measured at PW-D, TW-A, TW-B, TW-D, TW-1, and TW-4. Hydrographs for the pumping wells and observation wells are shown in

Appendix D. The constant rate test hydrograph for PW-D indicates that the water level in the pumping well stabilized quickly after pumping began. Distance-drawdown analysis for PW-D was performed on the drawdown data obtained at the end of the test. Analysis indicates that the calculated transmissivity at PW-D was 26,000 gpd/ft. The storage coefficient was 0.0046 and the specific capacity at the end of the test was approximately 14 gpm/ft dd. Water level in the pumping well rose to approximately 1 foot of the prepumping level within 1 hour after cessation of pumping.

RAW WATER SAFE YIELD OF SANDY CREEK WELL FIELD

Based on pumping tests conducted at PW-A, PW-C, and PW-D, the raw water safe yield of each well has been calculated. In determining well capacities, it was assumed that all three newly drilled wells and existing well PW-B would operate simultaneously. It was also assumed that the four wells would pump continuously for a 7-day period with no aquifer recharge. Given this design criteria, well capacities were calculated so that the water level within each well would remain at a safe level above the top of the well screen. Shown below are calculated safe yields of the four wells at the site. It is recommended that the permanent pumps at wells PW-A, PW-C, and PW-D are sized as shown.

Well	Capacity in gpm
PW-A	375
PW-B (Existing)	375
PW-C	250
PW-D	250
Total	1,250 gpm or 1.8 mgd

As can be seen on the above table, the safe yield of the four wells is 1.8 mgd. If the wells are operated in a manner differently than assumed, i.e., less than four wells pumping simultaneously, the safe yield per well will be somewhat greater. However, it is not recommended to install permanent pumps in the wells with capacities greater than those shown above. By doing this, the wells can be operated simultaneously if the need arises, while maintaining safe groundwater levels in the wells.

The above noted capacities are somewhat different than those estimated in a 1985 report entitled "Test Drilling and Test Pumping at Harless, Boso, and McPherson Properties," prepared by Burgess & Niple, Limited. In the 1985 report, flows at PW-C and PW-D were estimated at 350 gpm and 375 gpm, respectively. The lower flows recommended as a result of this study are primarily due to greater pumping interferences than earlier anticipated.

WELL FIELD CAPACITY COMPARED TO WATER USAGE

According to Lubeck Public Service District sources, the 1987 average daily water usage was 0.86 mgd, while peak demand was as high as 1.26 mgd. These demands can be met using two or three well combinations at the Sandy Creek well field. Average demand can be supplied by pumping wells PW-A and PW-C, or PW-B and PW-D. Capacity from both of these combinations will equal 0.9 mgd. This flow is greater than the 1987 average daily demand. Peak demand can be met using system storage and/or pumping a third well. Pumpage from three wells will total 1.26 or 1.44 mgd depending upon which well is used. These flows are likewise greater than 1987 peak usage.

Recommended well field operating procedures are to be able to meet peak daily water demand with the largest capacity well out of service. In this manner, emergency loss of pumpage and/or normal well maintenance will not affect the capability of meeting peak water demands. With four wells at the Sandy Creek well field, Lubeck can meet peak flows with one of the 375-gpm wells out of service.

Since average water usage can be supplied using one 375-gpm well and one 250-gpm well, it is recommended that the well field be operated in this manner. Therefore, PW-A and PW-C should operate in unison, while PW-B and PW-D should operate together. This procedure will also further minimize pumping interferences, as adjacent wells will not operate simultaneously.

SHELL

3.0 SITE BACKGROUND AND SETTING

3.1 Site Description and History

3.1.1 Site Setting and Adjacent Land Use

The Shell Belpre plant is located on an approximate 300-acre site on the north bank of the Ohio River (river mile 188.5) approximately 2.4 miles west of the city of Belpre, in Washington County, Ohio (Figure 1.1). The plant is located on a generally level terrace above the Ohio River at an elevation of approximately 630 ft above mean sea level (msl). To the south and west, the land drops steeply toward a lower river bank terrace at an elevation of approximately 600 ft msl. The plant site is bounded on the south by Ohio State Route 618 and the Ohio River; on the west by Davis Creek; on the north by U.S. Highway 50/Ohio Route 7; and on the east by Township Road 97, facilities owned by Nova Chemical Corporation, other commercial/industrial operations, and additional undeveloped property owned by Shell (Figures 3.1 and 3.2). Shell property extends south to the Ohio River where Shell operates a barge unloading facility and a pumphouse for intake of river water.

Prior to purchase and development by Shell, the current plant area was in agricultural and low-density residential use. As shown on Figure 3.2, Shell property extends beyond the plant boundaries to the east, south, and west. Areas south and west of the Shell property are currently used for cropland and grazing. Low-density residential development occurs west of the Shell property at Porterfield. Undeveloped, wooded areas are located north and immediately west of the plant, in the Davis Creek drainage area. Blennerhassett Island, a privately owned tract leased to the State of West Virginia for use as a state park and recreational area, is located in the Ohio River immediately south of the plant.

3.1.2 Operations History and Hazardous Waste Management

The Belpre Plant began operating in 1962. Throughout its history, the Shell plant has manufactured synthetic rubbers and, more recently, thermoplastic elastomers from styrene, isoprene, and/or butadiene in a cyclohexane solvent. Hazardous wastes generated during the manufacturing process have included primarily ignitable characteristic hazardous wastes classified as D001,

conditions has been conducted during the RA and RFI to facilitate assessment of the potential for migration of released site constituents in groundwater.

Together the RA and Phase II RFI work programs have included installation of 140 soil borings to depths ranging from 6 to 20 ft below ground surface (bgs), 14 additional monitoring wells screened at the top of the aquifer, and 3 additional monitoring wells screened at the base of the aquifer (see Table 3.1). The site monitoring network currently consists of 44 wells, including 4 screened at the base of the aquifer (see Table 3.2). Selected wells were field tested during the RA to assess aquifer hydraulic conductivity. Water levels in all wells have been measured to assess groundwater flow patterns. Surface water elevations have been measured in the Ohio River, Davis Creek, and on-site ponds to assess groundwater-surface water recharge and discharge relationships. The following paragraphs provide an updated description of the hydrogeology underlying the Belpre facility, incorporating recently acquired data.

3.2.2 Regional Hydrogeologic Setting and Local Groundwater Use

The Shell Belpre plant site is located on the upper terrace of alluvial fill on the northern side of the Ohio River glacial valley. The modern Ohio River occupies a narrow, meandering channel within glacial valley fill. Pleistocene terraces from the ancestral river occupy the higher elevations within the valley floor on both sides of the river. The stratigraphic sequence penetrated by borings and wells at the site consists primarily of gravel and sand, with silts and clays present in the upper part of the sequence. The alluvial deposits are underlain by Permian bedrock consisting of shaley sandstone and sandy shale.

Ohio River valley alluvial deposits comprise the dominant regional aquifer in eastern Ohio (Heath, 1984). A total of 39 wells registered with the Ohio Department of Natural Resources (ODNR) and West Virginia Department of Health and Human Resources were identified within the search area within a 1-mile zone around the Shell Belpre plant including 19 located on Blennerhassett Island owned by E.I. DuPont de Nemours & Co. No depth or construction information was available for the DuPont wells. Among the other wells identified, depths for all but three ranged from 45 to 108 ft bgs, indicating production from the alluvial aquifer. The ground surface elevation for three deeper wells (170 to 216 ft deep) is unknown; therefore it can not be confirmed they are screened in the upper alluvial aquifer.

land surface elevation. The manufacturing area of the plant, where most SWMUs and AOCs are located, is situated on the upper terrace, beneath which the depth to groundwater is typically 40 to 50 ft bgs. Beneath the lower terrace, adjacent to Davis Creek and the Ohio river, the depth to groundwater may be 5 ft or less. Overall, static water level elevations beneath most of the facility range from approximately 586 to 583 ft msl corresponding to a fairly flat gradient. Groundwater typically flows under unconfined conditions beneath most of the plant, with confined conditions occurring in lower-lying areas immediately adjacent to Davis Creek and the Ohio River.

Figure 3.4 indicates the general direction of groundwater flow to be toward the Ohio River and Davis Creek, with probable discharge into both bodies. Historical water level measurements indicate a generally consistent flow pattern beneath the Shell facility (see Appendix B). As shown by Figure 3.4, the gradient beneath most of the plant area is essentially flat (i.e., <0.001 ft/ft). Contours in the area of the slag ponds, near the western facility boundary, indicate probable recharge conditions with a radial flow gradient as great as 0.03 ft/ft. Apparent hydraulic mounding and a steeper gradient (as steep as 0.02 ft/ft) also occurs east of the plant, evidenced by measurements well MW-23, which is screened across a relatively silty section in the upper portion of the aquifer. The well is located in the vicinity of an ephemeral drainage which does not receive stormwater runoff from the Shell facility, but which may receive runoff from the Nova facility and from areas to the north. No mounding was evident in the vicinity of the South Runoff Pond.

Measurements of water levels in four monitoring well pairs screened at the top and base of the aquifer were collected to assess vertical hydraulic gradients. As shown on Figure 3.4, these measurements indicated a slight (0.01 ft/ft) downward gradient within the area of mounding associated with the slag ponds, and a slight (0.003 to 0.03 ft/ft) upward gradient elsewhere beneath the plant. Measurements of water levels in the four deep wells conform to potentiometric surface contours constructed from measurements in wells screened at the water table, confirming that the groundwater flow direction at the top and base of the aquifer is essentially the same.

Rising-head slug tests conducted in 6 wells during the RA yielded estimates of hydraulic conductivity for the alluvial aquifer ranging from 2.8×10^{-4} cm/sec (0.8 ft/day) to 5×10^{-2} cm/sec (147 ft/day) (GSI, 1998d). The 6 values yield a geometric mean value of 15 ft/day. (The low-range value, obtained at well

water classification are agricultural water supply, industrial water supply, primary contact recreation, and warm-water habitat.

Under Ohio EPA Permit No. 0IF00008*GD, Shell discharges treated wastewater (from Outfalls 002 and 003), non-contact cooling water and stormwater (from Outfall 001), and non-process area stormwater (from Outfall 004) to Davis Creek at a cumulative permitted flow of 58.3 cfs. Stormwater run-off also drains to Davis Creek and/or the Ohio River via Outfalls 008, 009, 010, 011, 012, 013, and 014 under the terms of the General Stormwater Permit section of the NPDES permit (see Figure 3.2).

Notes:

1) Data from a Shell Oil Company report entitled: "Geohydrological Site Assessment, Marietta Chemical Plant, Ohio", by William J. Crawford, dated 1/28/83; a Woodward-Clyde Consultants report, entitled "Final report on Lithologic, Chemical Plant in Belpre, Ohio", dated 3/21/96; a memorandum by Richard Lewis of Shell Development Company entitled "Observation Well Network Evaluation", dated 2/29/96; groundwater monitoring data ODNR well logs/drilling reports supplied by Shell Chemical Company.
2) Aquifer Zone Screened refers to the interval of the unconfined aquifer that is screened, referenced to the saturated interval. "Upper" refers to the upper 1/3 - 1/2 of the interval. "Lower" refers to the lower 1/3 - 1/2 of the interval. Thirteen of the wells completed in the upper part of the saturated interval have screens that straddle the average potentiometric surface elevations measured in the In the remaining 12 wells, the average potentiometric elevation is above the top of the well screen. MW-32D is the only lower aquifer completion and it is paired with MW-32S. This pair does not show the presence of a vertical gradient at that location in the plant.
3) Monitoring wells on the Shell Chemical Plant have been labeled variously in previous reports and analytical data. Permanent monitoring wells are referred to in this table with the prefix "MW-". MW-R-1 was originally intended as a MW-B-19 were installed originally as borings, later converted to monitoring wells. Because they have been previously referred to in maps and recovery well, thus the R-1 designation. MW-B-8 and analytical reports as "B-8" and "B-19", these labels are preserved in the new designations.
4) PVC = Polyvinyl chloride; GW = Gravel, sandy, well-graded; SP = Sand, gravelly, poorly-graded; MSL = Mean Sea Level
   USCS = Unified Soil Classification System; ML = Silt; SW = Sand, gravelly, well-graded
   CL = Silty clay; SM = Sand, silty; BGS = Below Ground Surface
5) Ground level and casing elevations were resurveyed during August, 1997, by Vernon Surveying Co, Marietta, Ohio.
6) Historic groundwater elevation statistics include all available data to September 1997.

MAJOR DIVISIONS			GRAPHIC SYMBOL	LETTER SYMBOL	TYPICAL DESCRIPTIONS
COARSE GRAINED SOILS MORE THAN 50% OF MATERIAL IS LARGER THAN NO. 200 SIEVE SIZE	GRAVEL AND GRAVELLY SOILS MORE THAN 50% OF COARSE FRACTION RETAINED ON NO. 4 SIEVE	CLEAN GRAVEL (LITTLE OR NO FINES)		GW	Well-graded gravels, gravel-sand mixtures, little or no fines
				GP	Poorly-graded gravels, gravel-sand mixtures, little or no fines
		GRAVELS WITH FINES (APPRECIABLE AMOUNT OF FINES)		GM	Silty gravels, gravel-sand-silt mixtures
				GC	Clayey gravels, gravel-sand-clay mixtures
	SAND AND SANDY SOILS MORE THAN 50% OF COARSE FRACTION PASSING NO. 4 SIEVE	CLEAN SAND (LITTLE OR NO FINES)		SW	Well-graded sands, gravelly sands, little or no fines
				SP	Poorly-graded sands, gravelly sands, little or no fines
		SANDS WITH FINES (APPRECIABLE AMOUNT OF FINES)		SM	Silty sands, sand-silt mixtures
				SC	Clayey sands, sand-clay mixtures
FINE GRAINED SOILS MORE THAN 50% OF MATERIAL IS SMALLER THAN NO. 200 SIEVE SIZE	SILTS AND CLAYS	LIQUID LIMIT LESS THAN 50%		ML	Inorganic silts and very fine sands, rock flour, silty or clayey fine sands or clayey silts with slight plasticity
				CL	Inorganic clays of low to medium plasticity, gravelly clays, sandy clays, silty clays, lean clays
				OL	Organic silts and organic silty clays of low plasticity
	SILTS AND CLAYS	LIQUID LIMIT GREATER THAN 50%		MH	Inorganic silts, micaceous or diatomaceous fine sand or silty soils
				CH	Inorganic clays or high plasticity, fat clays
				OH	Organic clays of medium to high plasticity, organic silts
HIGHLY ORGANIC SOILS				PT	Peat, humus, swamp soils with high organic contents

- 600 — Potentiometric surface contour, ft MSL, (C.I.= 1 ft)
- 584.93 — Potentiometric surface elevation (ft MSL) measured on 4/14/97
- Inferred Groundwater flow direction

NOTES:

1) The potentiometric surface was interpolated, based on the assumption that surface water in ponds, Davis Creek, and the Ohio River is in equilibrium with adjacent groundwater.
2) Potentiometric contours based on monitoring well casing elevation data from original well installations during 1982-1996.

HISTORIC AND RECENT GROUND WATER LEVEL DATA, SAMPLE SITE COORDINATES AND HISTORIC AQUIFER TEST DATA

WATER LEVEL DATA

Plant Site

Water level depths, water level elevation data for 1991, and Du Pont coordinates of existing on-site monitor and production wells and the new temporary monitor wells are presented in Table A-1. Leachate and soil sample site coordinates are presented in Table A-2, and 1990 ground water level elevation data are presented in Table A-3. Water levels were measured using a QED Sample-Pro electric water level meter, model 6000. Top of well casing and ground surface elevations and the Du Pont grid coordinates were measured by Vernon Surveying Company, Marietta, Ohio.

Ground water level elevations in 1991 were similar to those in 1990 (Tables A-1 and A-3). Ground water levels along the Ohio River were slightly higher as a result of high precipitation in 1991. The Ohio River water level stage on 12/12/91 measured 582.2 feet msl as compared to the mean of 582 feet msl. Ground water level elevations around the Du Pont-Lubeck Wellfield rose significantly in December because the wellfield had been shut down during the period from November 13, 1991 through December 26, 1991, during ownership transition from the Lubeck Public Water System to Du Pont's Washington Works Plant. Water level elevations in the Du Pont-Lubeck wells were not measured at this time. The water level elevations presented in Table A-1 represent average historic water levels observed during average pumping of 500 gpm. Du Pont will be pumping at a rate of 600 to 700 gpm. Therefore, the drawdowns and the cone of influence from these wells will be greater than what has been historically observed (see Figure 13).

In 1991, ground water level depths on the plant site ranged from about 12 feet to 70 feet below ground surface. The ground water is shallow (about 12 to 33 feet deep) along the riverbank where it is recharged directly from the Ohio River. Depths to ground water increase significantly to the south (about 60 to 70 feet deep) away from the riverbank. Ground water elevations are highest along the riverbank (at about 581 ft. msl), decreasing to about 552 ft. msl at the easternmost well in the East Well Field, to about 560 ft. msl at the Du Pont-Lubeck Wellfield. The general lateral hydraulic gradient across the plant site is about 0.004 ft/ft to the southwest. Much steeper gradients occur around the production water wells.

ASH004941

Local Landfill

Ground water levels at the Local Landfill vary significantly as a result of the topography and resultant drainages, extensive underlying shale, and limited saturated thicknesses of the surficial erosional soils and underlying sandstone zones. Ground water depths at the Local Landfill ranged from about 3 feet below ground surface in the upper erosional soils in an eastern drainage basin, to about 130 feet in the central part of the landfill. Ground water level elevations ranged from +625.28 ft. msl in the southwest corner of the landfill in the shallow weathered material, to +724.31 ft. msl in the sandstone zone in the south-central part of the landfill.

HISTORIC AQUIFER TEST DATA

Plant Site

Specific capacity data from Washington Works seven East Field Production wells and two of the Du Pont-Lubeck wells were used to estimate transmissivity for the upper principal aquifer which underlies the Washington Works plant site. These results are presented in Table A-4. The analytical technique used to compute these estimates is presented by Driscoll (1986), and assumes that for a water table aquifer, the transmissivity is approximately equal to 1500 times the specific capacity.

The computed transmissivity values for the aquifer at the East Well Field range from about 17,000 gpd/ft to 50,000 gpd/ft; and the transmissivity for the aquifer at the Du Pont-Lubeck Well Field is about 120,000 gpd/ft. Based on a saturated thickness of about 40 feet, the hydraulic conductivity of the principal aquifer on the plant site ranges from about 60 ft/day (2*10-2 cm/sec) to about 400 ft/day (1*10-1 cm/sec). The higher transmissivities and hydraulic conductivities probably occur in areas of cleaner gravel deposits.

Local Landfill

Permeability testing was conducted by the firm of Tetra Tech Richardson, Inc. (October, 1989). Packer testing was conducted on LLMW 4 from a depth of 40 feet to 136 feet. The results are detailed in their October, 1989 report, and indicate that the average permeability for the shales and sandstone units is around 10-5 cm/sec. Higher permeabilities of 10-4 cm/sec observed in the shale and siltstone may be due to secondary permeability from fracturing. Lower permeabilities of 10-6 cm/sec in the sandstone may be due to increased shale and clay. The low yields of the monitor wells at the Local Landfill verify that the underlying saturated zones yield very little water.

Ohio River Data from USGS Gage Station at Parkersburg, WV

DESCRIPTION:
Latitude 39°16'05", Longitude 81°33'50" NAD27
Wood County, West Virginia, Hydrologic Unit 05030202
Drainage area: 35,650 square miles
Contributing drainage area: 35,650.00 square miles,
Datum of gage: 560.60 feet above NAVD88.

* for K16-PW01: 621.74 = top of concrete floor. 623.24 = elevation of top of concrete pump base.
** This well can only be measured if the teflon process area is not in operation due to safety concerns.
" - ": not measured: inaccesible due to well pumps/pipes (for PWs); P08-MW01 was not sampled in 3Q due to a nearby line break.

Ft = Feet

* for K16-PW01: 621.74 = top of concrete floor. 623.24 = elevation of top of concrete pump base.

** This well can only be measured if the teflon process area is not in operation due to safety concerns.

- = not measured

Ohio River Data from USGS Gage Station at Parkersburg, WV

DESCRIPTION:
Latitude 39°16'05", Longitude 81°33'50" NAD27
Wood County, West Virginia, Hydrologic Unit 05030202
Drainage area: 35,650 square miles
Contributing drainage area: 35,650.00 square miles,
Datum of gage: 560.60 feet above NAVD88.

1.0 INTRODUCTION

A steady-state groundwater flow model was developed for the DuPont Washington Works facility (the site) in 1999. This model, which was completed as part of the RFI, was documented in the RCRA Facility Investigation Report (DuPont, 1999). The original groundwater flow model has been revised and expanded.

The primary objectives of the modeling work documented in this report included:

- Addressing EPA/ACOE comments on the previous groundwater flow model,
- Evaluating groundwater migration pathways at the site under current site and regional pumping conditions, and
- Predicting future groundwater migration pathways under various pumping scenarios.

Feedback was sought from experts with the U.S. Environmental Protection Agency (EPA), U.S. Army Corps of Engineers (ACOE), and U.S. Geological Survey during the redevelopment of the model. Meetings were held with these experts at key stages in model development including completion of the conceptual geologic model, following preliminary model calibration, and then after final model calibration in order to give the experts the opportunity to review the work completed at each stage and to solicit feedback.

The purpose of this report is to document the revised groundwater flow model for the DuPont Washington Works facility. The following sections describe the site setting, geology, and hydrogeology, and document the model set-up, calibration, and results.

2.0 SITE SETTING, GEOLOGY, AND HYDROGEOLOGY

2.1 Site Setting

The site is located on Washington Bottom in Washington, West Virginia. The location of the site and several surrounding properties are shown on Figure 1. The site, which is bounded on the north by the Ohio River, lies at the western (down-stream) end of Blennerhassett Island approximately between river miles 189 and 191. The DuPont site shares its southwestern boundary with another manufacturing facility operated by General Electric (GE).

2.2 Geology

The site lies within the Ohio River Valley and rests on Quaternary alluvial sediments that overly the Permian-aged Dunkard Group. The two predominant facies of the Ohio River alluvium that have been identified include coarse-grained Ohio River Alluvium (Pleistocene-aged glacial outwash deposits) and fine-grained Ohio River Alluvium (Holocene overbank deposits (Simard, 1989). The Pleistocene deposits consist primarily of coarse-grained sand and gravel while the Holocene deposits consist primary of interbedded and laminated silt, clay and fine-grained sand. Simard also identified three minor facies of the Ohio River Alluvium including tributary deposits (silt, sand and gravel), colluvial deposits (coarse sand, gravel, cobbles and boulders) and eolian sand and silt deposits. The Dunkard Group (bedrock) consists primarily of red and varicolored sandy shale; gray, green and brown sandstone; gray and light-gray siltstone; and minor beds of coal, claystone, black carbonaceous shale and limestone.

The facies of the Ohio River Alluvium formed in response to the glacial advances and retreats of the pre-, early- and late-Wisconsinan and were deposited as successive phases of aggradation and degradation of river valley alluvial materials. The coarse-grained Pleistocene alluvium was deposited as glacial outwash during the primary valley aggradation event following the glacial scouring of the valley into the bedrock floor. During the subsequent degredation and aggradation cycles of the Pleistocene, the glacial outwash sediments were partially removed, re-worked and then redeposited to a lower elevation than the previous cycle, thus forming a terrace. This process formed a series of Pleistocene-aged terrace surfaces within the Ohio River Valley. These surfaces were designated (youngest to oldest) as S4, S5, and S6 by Simard. With each subsequent degredation/aggradation cycle, additional fines were incorporated into the Pleistocene deposits due to continual influx of finer-grained fluvial sediments from tributaries of the Ohio River. As a result, the Pleistocene deposits become more highly re-worked and progressively finer-grained toward the center of the river valley, particularly in locations down-stream of significant tributaries (Simard, 1989). The total thickness of Pleistocene sediments at Washington Bottom ranges from about 80 feet beneath the highest Pleistocene terrace surfaces to about 15 feet beneath the current channel of the Ohio River.

The Pleistocene alluvial deposits are overlain by the finer-grained Holocene sediments. The silts, clays, and fine sands were deposited on the surface of the Pleistocene terraces as well as on a series of more recent floodplains, which formed in the center of the Ohio River Valley during the Holocene. The thickness of the Holocene sediments typically ranges from 5 to 15 feet over the Pleistocene terrace surfaces and 25 to 35 feet over the Holocene floodplains. Simard designated the Holocene floodplain surfaces as S1 through S3 and the modern floodplain of the Ohio River as S0. Figure 2, modified from Simard (1989), is a block diagram and idealized cross-section through the Ohio River valley depicting the complex set of Pleistocene terraces and Holocene floodplains which have formed in the valley.

Holocene floodplain surfaces and Pleistocene terrace surfaces were mapped using surface age and elevation data from Simard, 1989. A map of floodplain and terrace surfaces is shown in Figure 3. Individual floodplain and terrace surfaces were not differentiated. Due to damming of the river, the S0, S1, and S2 Holocene floodplain surfaces are now flooded along the reach of the Ohio River at Washington Bottom. The S3 surface remains above the current normal pool elevation of 582-ft. MSL. A thin strip of this surface remains on the south side of the river along Washington Bottom. More extensive expanses of this surface are present along the north side of the river at Little Hocking Water Association (WA), Blennerhassett Island, Shell Kraton, and Belpre. Additional expanses of this surface are present down-stream of Washington Bottom at Lubeck Public Service District (PSD). The remainder of the alluvial valley is occupied by the Pleistocene terrace surfaces.

A generalized north-south cross-section from the Little Hocking WA well field in Ohio, through the Ohio River and across the DuPont facility, is presented in Figure 4. This cross-section shows the floodplain and terrace surfaces, the Holocene silt and clay overbank deposits overlying the Pleistocene sand and gravel outwash deposits and the re-worked Pleistocene alluvium in the center of the river valley. The alluvial terrace deposits are underlain by a flat, river-scoured bedrock surface of the Dunkard Group that rises steeply and forms the valley walls to the North of Little Hocking Water Association and to the south of the DuPont facility (Figure 3).

2.3 Hydrogeology

Groundwater supplies in the region are obtained from the Dunkard Group bedrock and Ohio River alluvial terrace deposits. The saturated portion of the Ohio River alluvial terrace deposits comprise the principal regional aquifer used for water supply purposes. Production wells completed in this aquifer have been known to yield up to 500 gallons per minute (gpm) (Schultz, 1984). Based on these high yields, numerous industrial and commercial water supply companies obtain water from the alluvial aquifer.

The Holocene silts and clays support perched groundwater zones. Along the southern riverbank at the DuPont plant site on Washington Bottom, are seven monitoring wells that are completed in this perched groundwater zone. Groundwater elevations for these monitoring wells are typically 6 to 18 feet higher than elevations measured in monitoring wells completed in the underlying primary site water-table aquifer, which is significantly depressed as a results of pumping by DuPont and GE. During the February 2002

synoptic groundwater level event, groundwater elevations in the perched water table at the site ranged from 571.91 feet above mean sea level (MSL) to 582.09 feet MSL (Figure 5). Groundwater elevations in the underlying primary site water-table aquifer ranged from 558.24 to 566.61 feet MSL.

The Ohio River Alluvial Aquifer, which is the primary water-table aquifer in the area, occurs at a depth of about 60 to 70 feet below ground surface at the DuPont plant site. The saturated zone is approximately 30 to 40 feet thick, extending approximately to the surface of the underlying Dunkard Group bedrock. Numerous pumping tests have been completed in the alluvial aquifer in the Washington Bottom area as part of water supply investigations. The hydraulic conductivity of the alluvial aquifer in the area typically ranges from 100 to 300 ft./d. In contrast, the hydraulic conductivity of the underlying Dunkard Group bedrock aquifer is typically between 0.05 and 5 ft./d (see Section 4.3.1).

Natural recharge to the alluvial aquifer comes from various sources, including:

- Infiltration of precipitation falling directly on the alluvium
- Lateral movement of the river water through the alluvium
- Seepage from stream tributaries that discharge to the Ohio River
- Surface run-off from the outcrop areas of the Dunkard Group, which forms steep slopes adjacent to the uppermost Pleistocene terrace.

3.0 PRIMARY DATA SOURCES

Data was obtained from numerous sources for use in revising the Washington Works groundwater flow model. These sources and the nature of the data obtained from each source are summarized in Table 1 below.

Table 1. Primary Data Sources for the Groundwater Flow Model.

4.0 MODEL SET-UP

Groundwater flow in the Ohio River Alluvial Aquifer at the DuPont Washington Works facility and the surrounding area was simulated using United States Geological Survey's MODular Groundwater FLOW modeling code (MODFLOW, McDonald and Harbaugh, 1984). MODFLOW was selected because of its wide acceptance within the industry as well as its versatility in simulating various types of complex groundwater flow boundaries. The groundwater model was constructed and calibrated using Groundwater Vistas (v. 3.36), a graphical pre- and post-processor that interfaces with MODFLOW, published by Environmental Simulations, Inc. (ESI).

4.1 Model Domain and Discretization

The Washington Works Groundwater Model domain covers an area of 39.5 square miles, extending 41,568 feet east-west and 26,394 feet north-south. The origin of the finite difference grid is located at UTM Coordinates of 4,341,000 northing and 437,800 easting (UTM, NAD 27 meters). The finite difference model grid is shown on Figure 6.

The model domain was discretized as follows:

- 153 rows by 235 columns
- 3 layers
- 107,865 cells (69,705 active cells)
- Grid spacing: 25 m to 100 m (82 ft. to 328 ft.)

The Ohio River Alluvial Aquifer is represented in the model by layers 1 and 2, while the bedrock aquifer (minor aquifer) is simulated as layer 3. The vertical discretization and hydrostratigraphic units simulated in each layer is summarized in Table 2 below.

Table 2. Finite-Difference Grid Vertical Discretization.

Model Layer	Top Elevation (ft. above MSL)	Bottom Elevation (ft. above MSL)	Hydrostratigraphic Units Represented
Layer 1	Variable – based on topography	560	Fine-grained Holocene sediments Pleistocene Sands and Gravels Bedrock - Dunkard Group
Layer 2	560	535	Pleistocene Sands and Gravels Re-worked Pleistocene Sands and Gravels – main river channel Re-worked Pleistocene Sands and Gravels – Blennerhassett Island Bedrock - Dunkard Group
Layer 3	535	500	Bedrock - Dunkard Group

The base of layer 1 is set at an elevation of 560 ft. above MSL throughout the model layer. This elevation corresponds approximately to the elevation of the contact between the fine-grained Holocene sediments and the underlying Pleistocene sand and gravel beneath the Holocene floodplains. The top of layer 2 coincides with the base of layer 1. The base of layer 2, which is also constant throughout the model, is set at an elevation of 535 ft. above MSL. This elevation corresponds approximately to the elevation of the contact between the Pleistocene sand and gravel and the underlying shales of the Dunkard Group (bedrock) within the river valley. These contact elevations are based on well and soil boring logs from the DuPont Washington Works plant site, Blennerhassett Island, and Little Hocking WA (Figure 4).

4.2 Boundary Conditions

Under normal stress conditions, the alluvial aquifer would be expected to discharge to the Ohio River with infiltration being the predominant source of recharge to the aquifer. Due to the high volume of groundwater pumping from the alluvial aquifer along this reach of the river, the Ohio River is the main source of recharge to the alluvium within the area of the model domain while infiltration is a secondary recharge source. Correspondingly, discharge of groundwater from the alluvial aquifer within the area of the model domain occurs primarily through the numerous industrial and pubic supply wells. Minor volumes of groundwater recharge and discharge to the alluvial aquifer along several minor surface water features.

The treatment of these boundary conditions in the groundwater flow model is described in the following sections. The model boundary conditions are shown in Figure 7.

4.2.1 No Flow Boundaries

Many of the cells within the model domain are set as inactive (no flow cells). These cells are in areas of the domain where the alluvium is absent and the low permeability shales of the bedrock are present exclusively. The area of bedrock immediately surrounding the alluvial aquifer, both adjacent and below the alluvium, is included as active cells within the model to discretely simulate recharge to the alluvial aquifer from the bedrock.

The area of active bedrock cells laterally surrounding the alluvial aquifer was delineated based on the estimated locations of groundwater divides within the bedrock aquifer. The locations of the divides were estimated from surface topography.

Additional no flow cells were assigned to the center of the Ohio River in model layer 1 where the river bed elevation was below the base of that layer (560 ft. MSL). River bed elevation in each model cell was interpolated from Ohio River bathymetric data (US ACOE, 2002)

4.2.2 Ohio River

The Ohio River is simulated in the model as a MODFLOW river boundary. River boundary cells were set within the model domain based on the current river channel width and riverbed elevation. The river boundary cells representing the Ohio River were assigned to either model layer 1 or 2, depending on the elevation of the riverbed at the

center of each model cell. Where the river bed elevation was below the base of layer 1 (560 ft. MSL), the river boundary was assigned to layer 2 and the overlying cell in layer 1 was set as a no flow cell (inactive) as previously described.

River boundaries allow the simulation of groundwater recharge or discharge on the basis of the gradient between the predicted groundwater head surrounding the river cell and the specified river stage elevation. The volumetric rate of groundwater flow across the boundary is governed by the hydraulic gradient between the groundwater head and the river stage and the hydraulic conductance of the riverbed material. The conductance of the riverbed is calculated for each river cell independently, according to the following formula:

$$C_{RIV} = KLW/M$$

Where:

C_{RIV} = hydraulic conductance of the river-aquifer interconnection

K = hydraulic conductivity of the riverbed material

L = length of the riverbed within the model cell

W = width of the riverbed within the model cell

M = thickness of the riverbed within the model cell

Because entire model cells are contained within the Ohio River, the length and width of the riverbed within each river boundary cell was taken to be the length and width of the model grid cell. The thickness of the riverbed was assumed to be 5 feet. The hydraulic conductivity of the riverbed material, which was adjusted during model calibration, varied depending upon the nature of the geologic materials that the river cell was founded upon (riverbed K for river cells overlying Holocene silt and clay were lower than those overlying Pleistocene sand and gravel). The final riverbed hydraulic conductivity values for river cells are summarized in Table 3 below.

Table 3. Riverbed Hydraulic Conductivity Values.

Geologic Materials Under Riverbed	Hydraulic Conductivity of Riverbed (ft./d)
Holocene alluvium – silt, clay, fine sand	0.1
Re-worked Pleistocene alluvium – sand, gravel, silt	0.3
Re-worked Pleistocene alluvium at west end of Blennerhassett Island	30

The normal pool elevation for this reach of the Ohio River in 582 ft. above MSL. River elevations measured at the Little Hocking WA and Shell Kraton plant on August 21, 2002 were 582.24 and 582.05, respectively. The river elevation should be higher at the Shell Kraton plant than at Little Hocking WA, which is down-stream, indicating that there is some error in one or both of these measurements. Therefore, the normal pool elevation of 582 ft above MSL was used as the river stage elevation in the groundwater flow model. A constant river elevation was used throughout the model domain (e.g., no stream fall was simulated) due to river damming, which has led to relatively insignificant change in river stage elevation within the model domain.

4.2.3 Minor Surface Water Features

Numerous minor surface water features occur within the bedrock outcrop areas as well as on the alluvial terrace surfaces within the model domain. The majority of these features are ephemeral streams in which the flow is limited primarily to storm water run-off. The stream reaches within the bedrock outcrop area are included in the model as MODFLOW drain boundaries.

This boundary type is appropriate for simulating the ephemeral streams in the bedrock areas, which are minor discharge points for the bedrock aquifer but do not contribute significant recharge. Drain boundaries allow the simulation of groundwater discharge on the basis of gradient between the predicted head surrounding the drain and the specified drain elevation (i.e., the surface water elevation). Similar to river boundaries described previously, the rate of flow across the boundary is governed by the hydraulic gradient between the surrounding groundwater head and the drain stage elevation and the hydraulic conductance of the drain bed material (streambed). Contrary to river boundaries, drain boundaries will not contribute positive flow into the model domain under inward gradient conditions (e.g., if the surrounding heads are lower than the specified boundary head). The drain elevation assigned to each drain boundary cell was based on the topographic elevation along the stream at the center of the cell. The drain conductance in each boundary cell was calculated using estimated stream dimensions (length, width and bed thickness) and the streambed hydraulic conductivity. A nominal streambed hydraulic conductivity of 1 ft. / d was used so as not restrict groundwater discharge along these boundaries.

Three perennial streams are present within the model domain. These streams include Sandy Creek near Lubeck PSD, an unnamed stream across the Ohio River from Lubeck, and an unnamed stream that flows through the Shell Kraton facility on the north side of the Ohio River near Blennerhassett Island. It is likely that each of these streams provides some recharge to the alluvial aquifer and has some influence on the local groundwater elevations. Therefore, these streams were simulated as MODFLOW river boundaries to allow for the simulation of this recharge component. The river boundary elevation in each cell was based on the topographic elevation along the stream. The stream conductance in each river boundary cell was calculated using estimated stream dimensions (length, width and bed thickness) and a streambed hydraulic conductivity of 0.1 ft. / d, which is appropriate for the Holocene streambed sediments.

4.2.4 Pumping Wells

A total of 50 industrial and public water supply wells are located within the model domain. These wells, which are shown on Figure 8, are located at the following sites:

- GE (14 wells)
- DuPont Washington Works Plant (13 wells)
- Blennerhassett Island (12 wells)
- Lubeck PSD (6 wells)
- Little Hocking WA (4 wells)
- City of Belpre (1 well)

Forty-four of these wells were actively pumping during the collection of synoptic groundwater elevation measurements used for model calibration. Therefore, pumping is simulated at these 44 wells in the groundwater flow model. The pumping wells, which are all completed in the lower portion of the alluvial aquifer, are simulated in layer 2 of the model.

In most cases, pumping rates (ft^3/d) used in the model were calculated from total daily flows on February 02, 2002 (day of synoptic groundwater level measurements), assuming continuous operation. The exception is pumping rates for Little Hocking WA wells, which were not pumping during the collection of synoptic groundwater levels on February 02. Additional groundwater level measurements were collected on August 21, 2002 while the Little Hocking pumping wells were active (See Section 5.1 Calibration Strategy). Therefore, pumping rates for these wells were calculated from hourly system flows on August 21, 2002.

The majority of the DuPont water supply wells are monitored individually, including the East Well Field wells (331 to 337), Blennerhassett Island wells (435 to 446) and the Ranney collector well. The pumping rates for these wells were calculated from the total daily flow of each well. Due to model convergence problems associated with model cells going dry around groups of closely-spaced pumping wells, the individual rates for the East Well Field wells were totaled and re-apportioned equally among the seven wells. The DuPont Ranney collector well, which includes the central well and 6 lateral collector wells (horizontal), was simulated in the model as 5 individual wells with the pumping rate apportioned equally between them. The location of the 5 wells used to simulate the Ranney collector was based on the actual orientation and length of the 5 lateral collectors.

Flow rates are not monitored at individual wells in the DuPont-Lubeck Well Field. Thus the total flow rate for the field was calculated from the total daily flow and apportioned equally among the 5 wells (DL-1 to DL-5).

Total system abstraction rates for the Lubeck PSD and the City of Belpre were obtained from Monthly Operation Reports for these supply systems, which were provided by the West Virginia Department of Environmental Protection or Ohio Environmental Protection Agency (OHEPA). The total system flow rate for each system was calculated from the total daily abstraction and apportioned equally between the pumping wells.

Hourly flow rates for Little Hocking WA were provided by OHEPA. Flow rates for the time of day during which groundwater levels were measured at Little Hocking were used in the model. The total flow rate for the system was apportioned equally between wells PW-1, PW-2, and PW-3, all of which were pumping when the groundwater levels were measured (August 21,2002).

Pumping rate data for GE was unavailable. Pumping rates for the GE wells were estimated from the "normal" operational pumping rates for individual wells, which were provided for the majority of the wells by GE. The actual pumping rates usually vary somewhat from the "normal" operation rates. Therefore, the pumping rates for several of the GE wells were adjusted during model calibration to roughly match the observed draw-downs.

The pumping rates used in the model are summarized in Table 4 below.

Table 4. Model Pumping Rates.

Site	Well ID	Pumping Rate on Feb 02, 2002 (gpm)[1]	Model Pumping Rate (gpm)

GE[2]	Well 16	NA	0

1 - All pumping rates are based on measured daily flows from February 02, 2002 except for Little Hocking WA wells where August 21, 2002 hourly rates were used.
2 – Pumping rate data for GE wells was unavailable. Pumping rates for GE wells were estimated from design capacities and adjusted during model calibration.

4.3 Main Input Values

4.3.1 Hydraulic Conductivity

Distribution of hydraulic conductivity values used in the model was based on predicted sub-surface distribution of Holocene and Pleistocene aged alluvial sediments and depositional history of those sediments as described in Section 2.2 Site Geology. Model layer 1 was discretized vertically such that all fine-grained Holocene sediments occur within this model layer (See Section 4.1). The vertical discretization of model layer 2 was such that only the coarser grained Pleistocene sediments, which underlie the Holocene sediments and overlie the bedrock, occur within this model layer. The top of model layer 3 coincides with the estimated elevation of the top of the bedrock surface underlying the alluvium. Hydraulic conductivity zonation used in the model is shown in Figure 9.

The lateral distribution of hydraulic conductivity values in each model layer (zonation) reflects the predicted sub-surface distribution of alluvial sediments based on the terrace surface ages as previously described in Section 2.2. Areas of layer 1 that underlie Holocene aged floodplains in the central portion of the river valley were assigned hydraulic conductivity values appropriate for the silt and clay overbank deposits, which occur in the shallow sub-surface beneath the floodplains. Areas in both layer 1 and layer 2 underlying the higher Pliestocene-aged terraces were assigned conductivity values appropriate for the coarse sand and gravel glacial outwash deposits, which occur in the sub-surface in these areas. The areas of layer 2 beneath the existing Ohio River channel were assigned a lower conductivity than the surrounding Pleistocene sediments to account for the significant degree of re-working of the Pliestocene sediments and contribution of additional fines which has occurred in the center of the river valley. Hydraulic conductivity values assigned to model layer 3 were appropriate for the shales and sandstones of the Dunkard Group.

A range of appropriate hydraulic conductivity values was determined for each of the geologic units simulated in the flow model from available aquifer testing results and published literature values. Results from numerous aquifer pumping tests from water supply wells completed in the coarse-grained Pleistocene sand and gravels were considered in determining the appropriate range of values for these sediments. The appropriate range for the other geologic units (Holocene sediments, re-worked Pleistocene sediments, and bedrock) were estimated from published literature values. The conductivity value for each of the geologic units was adjusted during model calibration, but maintained within the range of conductivity values deemed appropriate for the unit. The range of appropriate hydraulic conductivity values for each geologic unit, the source of the conductivity data used, and the conductivity values assigned to each geologic unit in the groundwater flow model are presented in Table 5 below.

Table 5. Aquifer Hydraulic Conductivity Values.

Geologic Unit	Description	Range of K Values (ft./d.)				Model K Value (ft./d.)	Data Source(s)
		Number of Results	Min	Max	Geometric Mean		
Holocene Alluvial Sediments	Interbedded and laminated silt, clay, and fine sand	--	0.03	2.8	--	Kx,Ky = 1.0 Kv = 0.01	4
Pleistocene Alluvial Sediments	Coarse-grained sand and gravel	37	35	871	146	Kx,Ky = 300 Kv = 150	1, 2, 3, 6, 7, 8, 9
Pliestocene Sediments Underlying Blennerhassett Island	Coarse-grained sand and gravel	5	124	374	235	Kx,Ky = 200 Kv = 100	1, 6
Re-worked Pleistocene Alluvial Sediments	Interbedded sand and gravel with silt	--	2.8	284	--	Kx,Ky = 30 Kv = 3	4
Dunkard Group – Bedrock[1]	Interbedded shale and sandstone with minor limestone and coal beds	3	0.02	5.6	0.2	Kx,Ky = 0.1 Kv = 1 x 10^{-4}	5

Notes:

1. Results from Wood County only were used in the analysis. Hydraulic conductivity calculated from reported transmissivity and well depth.

4.3.2 Recharge

Distribution of recharge values used in the model was based on the predicted distribution of surficial soil types and thicknesses as described in Section 2.2 Site Geology. Pleistocene terraces, Holocene floodplains, and bedrock outcrop areas were assigned differing recharge rates to account for varying infiltration rates that would be anticipated in these areas due to differing soil types and thicknesses. An area of increased recharge was assigned along the outer edges of the Pleistocene terraces adjacent to the bedrock outcrop areas to account for increased infiltration of storm water run-off from the bedrock slopes in these areas. In addition, reduced recharge rates were assigned to large areas of impervious surface cover at the GE and DuPont plant sites. Recharge zonation used in the model is shown in Figure 10.

The recharge rates for the alluvial surfaces were based on estimates made by USGS (M. D. Kozar, oral communication). The rates for bedrock areas were estimated on the basis of topography and soil types present. A low infiltration rate was assigned to the bedrock areas to account for the steep slopes and low permeability of the surficial soils in these areas. Recharge rates were adjusted during model calibration. The rates used in the groundwater flow model are presented in Table 6 below.

Table 6. Model Recharge Rates.

Model Area	Recharge Rate (in. / yr.)
Holocene floodplains	4
Pleistocene terraces	8
Pleistocene terraces along bedrock outcrop	20
Bedrock and areas of impervious surface cover	0.1

5.0 GROUNDWATER MODEL CALIBRATION

5.1 Calibration Strategy

The steady-state groundwater flow model was calibrated against two sets of synoptic groundwater elevation measurements that were collected specifically for use in model calibration. The first set was collected on February 02, 2002. During this event, groundwater levels were measured in a total of 84 observation wells. Levels were measured at the following sites:

- DuPont Plant (44 wells)
- Blennerhassett Island (8 wells)
- Little Hocking WA (8 wells)
- Lubeck PSD (6 wells)
- GE Plant (13 wells)
- Shell Kraton Plant (5 wells)

It was determined that the pumping wells at Little Hocking WA were inactive at the time of measuring groundwater levels on February 02, 2002. Therefore, a second round of groundwater level measurements was made at the Little Hocking WA site on August 21, 2002 to obtain groundwater elevations for this site under active pumping conditions. Groundwater levels were also measured in selected wells at the DuPont Plant (15 wells) and the Shell Kraton Plant (1 well) for comparison between the two monitoring events.

The extent of seasonal variation in groundwater elevation between the two monitoring events was determined by comparing groundwater elevations from the two events from well MW-11 at the Shell Kraton Plant. This well was used for the evaluation because it was the only well monitored during both events that was unlikely to be influenced by pumping activities DuPont and Little Hocking WA. The groundwater elevation decreased by 0.55 feet at MW-11 between the February and August monitoring events. This seasonal variation is likely to be insignificant relative the variation in groundwater elevation that occurs in response to changes in pumping rates within the model domain.

Given the small seasonal variation observed in groundwater elevation, the two sets of groundwater elevations were combined and used for model calibration targets (Figure 11). With the exception of those from Little Hocking WA, groundwater elevations from February 02, 2002 were used as the calibration targets in the model. The August 21, 2002 groundwater elevations from the Little Hocking WA site were used as model calibration targets in place of those from February in order to calibrate the model against groundwater elevations at this site under the influence of active pumping. Similarly, pumping rates from February 02, 2002 were used for all pumping wells other than those at Little Hocking WA where the August 21, 2002 rates were used instead (see Section 4.2.4 Pumping Wells).

5.2 Calibration Results

The results of the model calibration indicate that the groundwater flow model is accurately predicting the groundwater heads in areas where groundwater elevation data is available. The overall success of model calibration was measured in terms of the error (residual) between the observed (measured) groundwater elevation or head at each calibration target (observation well) and the head computed by the model at the target location. Calibration target residuals from the calibrated flow model along with a plot of observed versus calculated head are shown in Figure 12. The plot of observed versus computed heads shows a very good correlation between observed and computed head for a regional-scale groundwater flow model.

The success of model calibration can also be demonstrated through statistical analysis of the errors between observed and computed heads (target residuals). One particular measure is the overall residual error expressed as the percentage of the range in observed head, which is calculated as standard deviation of the residuals divided by the observed range in head. In this case, the standard deviation is 9.9% of the observed range. A result of 10% or less is generally considered to represent a good calibration. Table 7 below summarizes the results of the statistical analysis of the target residuals.

Table 7. Statistical Summary of Model Calibration Errors (Residuals).

Statistical Operation	Result
Residual Mean (ft.)	0.104
Residual Standard Deviation (ft.)	3.285
Sum of Squared Residuals (ft^2)	907.491
Absolute Residual Mean (ft.)	2.308
Minimum Residual (ft.)	-9.249
Maximum Residual (ft.)	12.060
Range in Observed Head (ft.)	33.350
Residual Standard Deviation / Range in Observed Head (ft./ft.)	0.099

6.0 MODEL RESULTS

6.1 Mass Balance

The total water balance (mass balance) of the groundwater flow model indicates very little error in the simulation. The total error (total inflow minus total outflow) is less than 0.01 percent. A summary of the mass balance for the groundwater flow model is shown in Table 8 below.

Table 8. Mass Balance Summary.

Component	In	Out
Storage	0	0
Constant Head	0	0
Wells	0	20,818,613
Drains	0	3,947
Recharge	4,343,758	0
River Leakage	17,581,300	1103300
Total	21,925,058	21,925,860
Absolute Error (In – Out)		-802
Percent Discrepancy		-0.0037

6.2 Current Pumping Conditions

The groundwater flow model is calibrated to observed groundwater elevations under the existing pumping conditions at sites within the model domain (as of February 02, 2002). The computed heads for the calibrated flow model for layers 1, 2 and 3 are shown in Figures 13, 14, and 15, respectively.

With the exception of local areas surrounding major pumping centers, the computed heads within the Pleistocene alluvium in layers 1 and 2 are approximately the same. Computed heads in the Holocene alluvium in layer 1 are slightly higher (less than 1 foot) than in the underlying Pleistocene alluvium. A slight downward gradient is predicted in most areas of the alluvial aquifer in response to pumping from model layer 2. Increased downward gradient is predicted in layer 2 locally around pumping centers.

A groundwater divide is predicted beneath the Ohio River in the Pleistocene alluvium (layer 2). A divide is predicted beneath the main channel and on either side of Blennerhassett Island. The divides separate the areas of significant draw-down centered

at DuPont and GE, Blennerhassett Island, and Little Hocking WA from one another. Due to the presence of this divide, no groundwater migration pathway is predicted beneath river in the alluvial aquifer under the current pumping rates. The only exception is at the east end of Blennerhassett Island where the river has not incised as deeply into the underlying Pleistocene alluvium (the entire width of the river boundary remains in layer 1). At this location, a groundwater divide is absent in layer 2 and the cone of depression from Belpre extends southward across the river. Figure 14a shows the approximate extent of the capture zones associated with the DuPont and Little Hocking Pumping systems.

Computed heads in bedrock areas generally decrease from layer 1 to layer 3. An upward gradient from the bedrock to the overlying alluvial aquifer is predicted throughout most of the domain, with the highest gradient predicted near pumping centers. The highest predicted upward gradient is about 9 ft. at Blennerhassett Island.

A groundwater divide is not predicted in the bedrock aquifer beneath the Ohio River. Groundwater flow from Little Hocking WA to the DuPont and GE plant sites is predicted in the bedrock aquifer. However, the bedrock aquifer is simulated discretely in the model in order to provide recharge to the overlying alluvial aquifer. Groundwater elevations in the bedrock aquifer were not calibrated and therefore should be considered an approximation. Simplification of complex stratification of the bedrock aquifer may have resulted in inaccuracies in predicted groundwater elevations in the bedrock aquifer. This simplification has little or no effect on predictions of groundwater flow in alluvium.

The majority of the groundwater in the alluvial aquifer at the DuPont plant site is currently being captured by the on-site pumping activities. Some limited off-site groundwater migration may be occurring in the northwest corner of the DuPont plant site in response to pumping at GE wells 3 and 4.

6.3 No DuPont Pumping

A simulation was run to determine the influence that pumping activities at the DuPont plant and Blennerhassett Island are having on groundwater elevations at surrounding sites. To complete this simulation, pumping wells at the DuPont plant and at Blennerhassett Island were tuned-off while leaving all other pumping well rates as per the calibrated simulation. The predicted heads in model layer 2 for this scenario are shown in Figure 16.

The model predicts an increase in groundwater heads in the central areas of the DuPont and GE plant sites of approximately 15 and 9 ft., respectively. An increase of approximately 2 ft. is predicted at Lubeck PSD.

The model predicts no change in groundwater heads at Little Hocking WA, Shell Kraton, or Belpre would occur in response to cessation in pumping by DuPont. Conversely, this simulation suggests strongly that current pumping activities at the DuPont plant and Blennerhassett Island are not influencing groundwater heads at these sites.

6.4 No GE Pumping

Similar to the previously described simulation, a simulation was run to investigate the influence that pumping activities at the GE plant are having on groundwater elevations at surrounding sites. To complete this simulation, pumping wells at the GE plant were tuned-off while leaving all other pumping well rates as per the calibrated simulation. The predicted heads in model layer 2 for this scenario are shown in Figure 17.

The model predicts an increase in groundwater heads in the central areas of the DuPont and GE plant sites of approximately 10 and 16 ft., respectively. An increase of approximately 3.5 ft. is predicted at Lubeck PSD.

Again, the model predicts no change in groundwater heads at Little Hocking WA would occur in response to cessation in pumping by GE.

6.5 No Pumping by DuPont or GE

The previous 2 simulations were combined to investigate the influence that pumping at Little Hocking WA would have on groundwater elevations at Washington Bottom if both DuPont and GE ceased pumping activities. To complete this simulation, pumping wells at the DuPont and GE plant sites were tuned-off while leaving all other pumping well rates as per the calibrated simulation. The predicted heads in model layer 2 for this scenario are shown in Figure 18.

The model predicts an increase in groundwater heads in the central areas of the DuPont and GE plant sites of approximately 22 and 24 ft., respectively, which is equivalent to the amount of draw-down. An increase of approximately 4 ft. is predicted at Lubeck PSD.

Again, the model predicts no change in groundwater heads at Little Hocking WA would occur in response to cessation in pumping by DuPont and GE. However, with no pumping on the south side of the Ohio River, the model predicts that the groundwater divide below the river would be overcome by pumping at Little Hocking WA and the capture zone for that site would extend across the river to the south.

6.6 No Little Hocking WA Pumping

A final simulation was run to determine the influence that pumping activities at the Little Hocking WA are having on groundwater elevations at surrounding sites. To complete this simulation, pumping wells at Little Hocking were tuned-off while leaving all other pumping well rates as per the calibrated simulation. The predicted heads in model layer 2 for this scenario are shown in Figure 19.

The model predicts an increase in groundwater heads in the central area of the Little Hocking well field of approximately 7-ft. An increase in groundwater elevation of about 0.5 ft. is predicted at the Shell Kraton site. No change in groundwater elevation is predicted at Belpre, Blennerhassett Island, the DuPont and GE plant sites, or at Lubeck PSD in response to cessation of pumping at Little Hocking.

Similar to the previous simulation, the model predicts that with no pumping on the north side of the Ohio River, the groundwater divide below the river would be overcome and the DuPont plant capture zone would extend across the river to the north.

7.0 SENSITIVITY ANALYSIS

A sensitivity analysis was completed to determine the sensitivity of the model to uncertainties in the primary input parameters including hydraulic conductivity, recharge, and river boundary conductance. This analysis involved perturbing the input value for a single input parameter by fixed increments and re-running the model. The overall calibration error from each of the sensitivity runs were then evaluated and compared to determine the relative sensitivity of the model to errors in each of the main input parameters.

For each input parameter, multiplication factors of 0.25, 0.75, 1.0, 1.25, and 1.5 were used in the sensitivity analysis.

The input values perturbed during the sensitivity analysis and the relative sensitivity of the model to each value are summarized in Table 9 below. Graphs of the absolute residual mean and mean change in computed head for each input parameter tested during the sensitivity analysis are shown in Figure 20.

The sensitivity analysis indicates that the model is most sensitive to uncertainties in the hydraulic conductivity value assigned to the re-worked Pleistocene alluvium beneath the Ohio River. The reduced conductivity of this unit serves to restrict the flow of groundwater beneath the river and thus strongly influences the response to pumping predicted by the model.

Table 9. Sensitivity Analysis Results.

Input Parameter	Geologic Unit or Area	Relative Model Sensitivity (ranked from 1 [highest] to 10 [lowest])
Hydraulic Conductivity	Holocene alluvium	7
	Pliestocene alluvium	2
	Pliestocene alluvium – Blennerhassett Island	6
	Re-worked Pliestocene alluvium	1
Recharge	Holocene floodplains	10
	Pleistocene terraces	4
	Pleistocene terraces along bedrock outcrop	5
River Boundary Conductance	Holocene alluvium	8
	Re-worked Pleistocene alluvium	3
	Re-worked Pleistocene alluvium at west end of Blennerhassett Island	9

8.0 MODEL CONCLUSIONS

The primary conclusions of the revised Washington Works Groundwater Flow Model are summarized as follows:

- The Ohio River is creating a groundwater divide within the Pleistocene sediments beneath the river. Due to the presence of this divide, no groundwater migration pathway is predicted beneath river in the alluvial aquifer under the current pumping rates at the various pumping centers simulated in the model.
- A groundwater divide is not predicted in the bedrock aquifer beneath the Ohio River. Groundwater flow from Little Hocking WA to the DuPont and GE plant sites is predicted in the bedrock aquifer. However, groundwater elevations in the bedrock aquifer were not calibrated and should be considered an approximation.
- The majority of the groundwater in the alluvial aquifer at the DuPont plant site is currently being captured by the on-site pumping activities. Some limited off-site groundwater migration may be occurring in the northwest corner of the DuPont plant site in response to pumping at GE wells 3 and 4.
